Introduction to the AWS Flow Framework for Java

Amazon Simple Workflow Service (Amazon SWF) provides a powerful and flexible way for developers to implement distributed asynchronous workflow applications. The AWS Flow Framework is a programming framework that simplifies the process of implementing a distributed asynchronous application while providing all the benefits of Amazon SWF. It is ideal for implementing applications to address a broad range of scenarios including business processes, media encoding, long-running tasks, and background processing.

With the AWS Flow Framework, you can focus on implementing your workflow logic. Behind the scenes, the framework uses the scheduling, routing, and state management capabilities of Amazon SWF to manage your workflow's execution and make it scalable, reliable, and auditable. AWS Flow Framework-based workflows are highly concurrent; they can be readily distributed across multiple components which can run as separate processes on separate computers and be scaled independently. The application can continue to progress if any of its components are running, making it highly fault tolerant.

This section introduces the AWS Flow Framework by walking you through a series of simple applications that introduce the basic programming model and API. The example applications are based on the standard introduction to C and related programming languages: an application that prints "Hello World!" to the console. Here is a typical Java implementation:

```
public class HelloWorld {
   public static void main(String[] args) {
      System.out.println("Hello World!");
   }
}
```

The following is a brief description of the walkthroughs. They include complete source code so you can implement and run the applications yourself. Before starting, you should first configure your development environment and create and create and configure an AWS Flow Framework for Java project, as described in Setting up the Development Environment (p. 2).

- HelloWorld Application (p. 6) introduces workflow applications by implementing Hello World! as a standard Java application but structuring it like a workflow application.

- HelloWorldWorkflow Application (p. 8) uses the AWS Flow Framework for Java to convert HelloWorld into an Amazon SWF workflow.
- HelloWorldWorkflowAsync Application (p. 20) modifies `HelloWorldWorkflow` to use an *asynchronous workflow* method.
- HelloWorldWorkflowDistributed Application (p. 23) modifies `HelloWorldWorkflowAsync` so that the workflow and activity workers can run on separate systems.
- HelloWorldWorkflowParallel Application (p. 25) modifies `HelloWorldWorkflow` to run two activities in parallel.

Setting up the AWS Flow Framework for Java Development Environment

The AWS Flow Framework for Java is provided in the AWS SDK for Java. You can install the AWS SDK for Java in one of the following ways:

- Installing the AWS Toolkit for Eclipse (p. 2)
- Installing the AWS SDK for Java (p. 3)

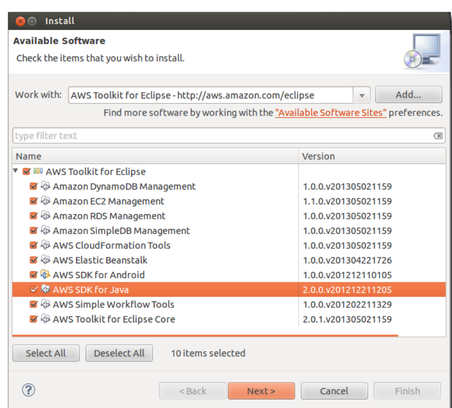
The AWS Flow Framework for Java documentation assumes that you use the recommended Eclipse development environment with the AWS Toolkit for Eclipse.

Important
The AWS Flow Framework for Java works *only* with Java 6 (JDK 1.6) and AspectJ; Java 7 (JDK 1.7) is not currently supported.

Installing the AWS Toolkit for Eclipse

Installing the AWS Toolkit for Eclipse is the simplest way to get started with the AWS Flow Framework for Java. For information about installing the AWS Toolkit for Eclipse, see the AWS Toolkit for Eclipse Getting Started Guide.

Important
While installing the AWS Toolkit for Eclipse, *be sure to install the Amazon SWF Tools*, as shown in the following screenshot of Eclipse's **Install New Software** dialog:



This is necessary to properly build AWS Flow Framework projects in Eclipse.

Installing the AWS SDK for Java

If you are not using Eclipse, you can download the AWS SDK for Java from http://aws.amazon.com/sdkforjava/. To build your project from the command line, `aws-java-sdk-flow-build-tools-1.4.7.jar` must be in the classpath.

For an example of a properly-configured command line Ant build file, see `build.xml` in the SDK's `samples/AwsFlowFramework` directory.

Creating an AWS Flow Framework for Java Project

To create an AWS Flow Framework for Java project

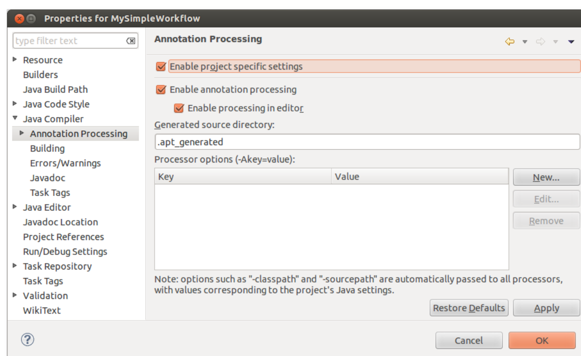
1. Configure Eclipse to show the Java perspective, which includes **Package Explorer**.
2. Click **File** > **New** > **AWS Java Project** and create a new project.
3. Configure the project for AWS Flow Framework for Java, as described in the following sections. These procedures were tested with Eclipse 4.3 (Kepler) and Java Development Kit (JDK) 1.6.

Enable Annotation Processing

The AWS Flow Framework for Java includes an annotation processor that generates several key classes based on annotated source code.

To enable annotation processing

1. In **Package Explorer**, right-click the project and select **Properties**.
2. In the **Properties** dialog box, navigate to **Java Compiler** > **Annotation Processing**.
3. Check **Enable project specific settings** and **Enable annotation processing**, as shown in the following screenshot.



> **Note**
> You may need to rebuild your project after enabling annotation processing.

Add the AWS Flow Framework for Java JAR to the Build Path

If you installed the AWS Toolkit for Eclipse, the AWS Flow Framework for Java JAR file, should be in your build path. If not, you must add it manually.

To add the AWS Flow Framework for Java JAR file to the build path

1. In **Package Explorer**, right-click your project, and select **Build Path** > **Configure Build Path**.
2. On the **Properties** dialog box's **Libraries** tab, click **Add External JARs**.
3. Navigate to the AWS SDK's lib directory, select aws-java-sdk-*version*.jar and click **Open** to add the JAR to the build path; *version* is the AWS SDK version number. This documentation is based on AWS SDK version 1.4.7 (aws-java-sdk-**1.4.7**.jar).

Enable and Configure AspectJ

Certain AWS Flow Framework for Java annotations such as `@Asynchronous` require AspectJ. You don't have to use AspectJ directly, but you must enable it by using either of the following procedures. The recommended approach is load-time weaving.

AspectJ Load-Time Weaving (Recommended)

To enable AspectJ load-time weaving designate the AspectJ JAR file as a Java agent.

To add the AspectJ Java agent

1. On the **Window** menu, select **Preferences**.
2. In the **Preferences** dialog box, navigate to **Java** > **Installed JREs**.
3. Select the appropriate JRE and click **Edit**.
4. Add the following line to the **Default VM Argument** text box:

   -javaagent:<*local directory containing the AWS SDK for Java*>**/third-party/aspectj-1.6/aspectjweaver.jar**

   Note
   Both the AWS Toolkit for Eclipse and the AWS SDK for Java install `aspectjweaver.jar` in your `aws-java-sdk/`*`version`*`/third-party/aspectj-1.6` directory, where *version* corresponds to the installed AWS SDK version number.

To configure AspectJ for AWS Flow Framework for Java, add an `aop.xml` file to the project.

To add an aop.xml file

1. Add a `META-INF` directory to your project's src directory.
2. Add a file named `aop.xml` to `META-INF` with the following contents.

```
<aspectj>
   <aspects>
      <!-- declare two existing aspects to the weaver -->
     <aspect name="com.amazonaws.services.simpleworkflow.flow.aspectj.Asyn
chronousAspect"/>
     <aspect name="com.amazonaws.services.simpleworkflow.flow.aspectj.Expo
nentialRetryAspect"/>
   </aspects>
   <weaver options="-verbose">
      <include within="<expression to match your types>"/>
   </weaver>
</aspectj>
```

The `within` attribute value depends on how you name your project's packages. For example, if all your project's packages are named *MySimpleWorkflow.XYZ*, set the `within` attribute like this:

```
...
   <weaver options="-verbose">
      <include within="MySimpleWorkflow..*"/>
   </weaver>
...
```

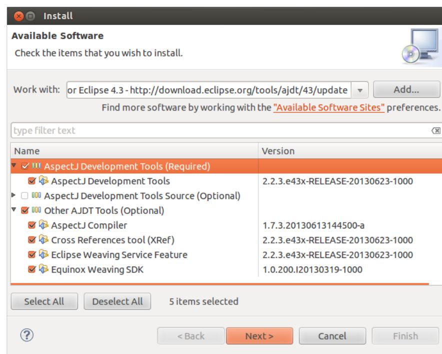
AspectJ Compile-Time Weaving

To enable and configure AspectJ compile-time weaving, you must first install the AspectJ developer tools for Eclipse, which are available from http://eclipse.org/ajdt/downloads/.

To install the AspectJ Developer Tools in Eclipse

1. On the **Help** menu, click **Install New Software**.
2. In the **Available Software** dialog box, enter http://download.eclipse.org/tools/ajdt/*version*/update, where *version* represents your Eclipse version number. For example, if you are using Eclipse 4.3 (Kepler), you would enter: http://download.eclipse.org/tools/ajdt/**43**/update.

   Important
   Be sure that the AspectJ version matches your Eclipse version, or installation of AspectJ will fail.
3. Click Add to add the location. Once the location is added, the AspectJ developer tools will be listed.



4. Select all of the AspectJ developer tools and click Next to install them.

You must then configure your project.

To configure a project for AspectJ compile-time weaving

1. In **Package Explorer**, right-click your project and select **AspectJ Tools**, then **Convert to AspectJ Project**.
2. In the **Properties** dialog box, click **AspectJ Build** and then click the **Aspect Path** tab.
3. Click **Add External JARs** and add the add the AWS SDK for Java JAR file to your project's **Aspect Path**.

Note

The AWS Toolkit for Eclipse installs the AWS SDK for Java JAR file in your workspace, in the `.metadata/.plugins/com.amazonaws.eclipse.core/aws-java-sdk/AWS Version/lib` directory, where you replace *AWS Version* with the installed AWS SDK version number. Otherwise, you can use the JAR file that is included with the regular AWS SDK installation, which is in the `lib` directory.

Working around issues with AspectJ and Eclipse

The AspectJ Eclipse plug-in has an issue that can prevent generated code from being compiled. To work around this issue, first *remove* AspectJ and then *re-convert* your project:

1. Right-click your project, click **AspectJ Tools**, **Remove AspectJ Capability**, and then click **Yes** to confirm.
2. Right-click your project, click **Configure**, then **Convert to AspectJ Project**.

HelloWorld Application

The HelloWorld application introduces the basics of workflow applications. It is structured as and works much like an AWS Flow Framework for Java workflow application, but is implemented as a conventional Java application that runs locally as a single process. Although it might seem like an overly complicated way to perform a simple task, HelloWorld provides a convenient way to introduce the basic structure and behavior of a workflow application and it can be converted to an AWS Flow Framework for Java application with only modest changes.

A workflow application consists of three basic components.

- An *activities worker* supports a set of *activities*, each of which is a method executes independently to perform a particular task.
- A *workflow worker* orchestrates the activities' execution and manages data flow. It is a programmatic realization of a *workflow topology*, which is basically a flow chart that defines when the various activities execute, whether they execute sequentially or concurrently, and so on.
- A *workflow starter* starts a workflow instance, called an *execution*, and can interact with it during execution.

HelloWorld is implemented as three classes and two related interfaces, which are described in the following sections. Before starting, you should set up your development environment and create a new AWS Java project as described in Setting up the Development Environment (p. 2). The packages used for the following walkthroughs are all named helloWorld.*XYZ*. To use those names, set the **within** attribute in aop.xml as follows:

```
...
<weaver options="-verbose">
<include within="helloWorld..*"/>
</weaver>
...
```

To implement HelloWorld, create a new Java package in your AWS SDK project named `helloWorld.HelloWorld` and add the following files:

- An interface file named `GreeterActivities.java`
- A class file named `GreeterActivitiesImpl.java`, which implements the activities worker.

- An interface file named `GreeterWorkflow.java`.
- A class file named `GreeterWorkflowImpl.java`, which implements the workflow worker.
- A class file named `GreeterMain.java`, which implements the workflow starter.

The details are discussed in the following sections and include the complete code for each component, which you can add to the appropriate file.

HelloWorld Activities Worker

HelloWorld breaks the overall task of printing a "Hello World!" greeting to the console into three tasks, each of which is performed by an *activity method*. The activity methods are defined in the `GreeterActivities` interface, as follows.

```
public interface GreeterActivities {
public String getName();
public String getGreeting(String name);
public void say(String what);
}
```

HelloWorld has one activity worker, `GreeterActivitiesImpl`, which implements the `GreeterActivities` methods, as follows:

```
public class GreeterActivitiesImpl implements GreeterActivities {
@Override
public String getName() {
   return "World";
}

@Override
public String getGreeting(String name) {
   return "Hello " + name + "!";
}

@Override
public void say(String what) {
   System.out.println(what);
}
}
```

Activities are independent of each other and can often be used by different workflows. For example, any workflow can use the `say` activity to print a string to the console. Workflows can also have multiple activity workers, each performing a different set of tasks.

HelloWorld Workflow Worker

To print "Hello World!" to the console, the activity tasks must execute in sequence in the correct order with the correct data. The HelloWorld workflow worker orchestrates the activities' execution based on a simple *linear workflow topology*, which is shown in the following figure.

The three activities execute in sequence, and the data flows from one activity to the next.

The HelloWorld workflow worker has a single method, the workflow's entry point, which is defined in the `GreeterWorkflow` interface, as follows:

```
public interface GreeterWorkflow {
public void greet();
}
```

The `GreeterWorkflowImpl` class implements this interface, as follows:

```
public class GreeterWorkflowImpl implements GreeterWorkflow{
private GreeterActivities operations = new GreeterActivitiesImpl();

public void greet() {
   String name = operations.getName();
   String greeting = operations.getGreeting(name);
   operations.say(greeting);
}
}
```

The `greet` method implements HelloWorld topology by creating an instance of `GreeterActivitiesImpl`, calling each activity method in the correct order, and passing the appropriate data to each method.

HelloWorld Workflow Starter

A *workflow starter* is an application that starts a workflow execution, and might also communicate with the workflow while it is executing. The `GreeterMain` class implements the HelloWorld workflow starter, as follows:

```
public class GreeterMain {
public static void main(String[] args) {
   GreeterWorkflow greeter = new GreeterWorkflowImpl();
   greeter.greet();
}
}
```

`GreeterMain` creates an instance of `GreeterWorkflowImpl` and calls `greet` to run the workflow worker. Run `GreeterMain` as a Java application and you should see "Hello World!" in the console output.

HelloWorldWorkflow Application

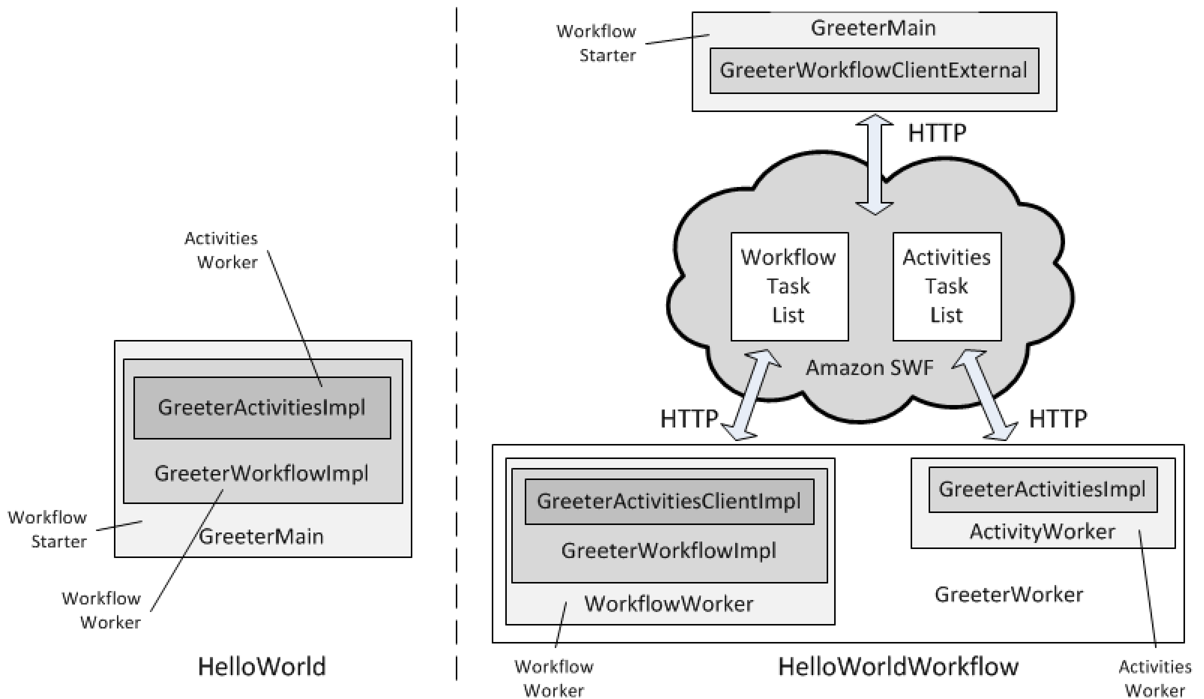
Although HelloWorld is structured like a workflow, it differs from an Amazon SWF workflow in several key respects:

Conventional and Amazon SWF Workflow Applications

HelloWorld	Amazon SWF Workflow
Runs locally as a single process.	Runs as multiple processes that can be distributed across multiple systems, including EC2 instances, private data centers, client computers, and so on. They don't even have to run the same operating system.
Activities are synchronous methods, which block until they complete.	Activities are represented by asynchronous methods, which return immediately and allow the workflow to perform other tasks while waiting for the activity to complete.
The workflow worker interacts with an activities worker by calling the appropriate method.	Workflow workers interact with activities workers by using HTTP requests, with Amazon SWF acting as an intermediary.
The workflow starter interacts with workflow worker by calling the appropriate method.	Workflow starters interact with workflow workers by using HTTP requests, with Amazon SWF acting as an intermediary.

You could implement a distributed asynchronous workflow application from scratch, for example, by having your workflow worker interact with an activities worker directly through web services calls. However, you must then implement all the complicated code required to manage the asynchronous execution of multiple activities, handle the data flow, and so on. The AWS Flow Framework for Java and Amazon SWF take care of all those details, which allows you to focus on implementing the business logic.

HelloWorldWorkflow is a modified version of HelloWorld that runs as an Amazon SWF workflow. The following figure summarizes how the two applications work.



HelloWorld runs as a single process and the starter, workflow worker, and activities worker interact by using conventional method calls. With `HelloWorldWorkflow`, the starter, workflow worker, and activities worker are distributed components that interact through Amazon SWF by using HTTP requests. Amazon

SWF manages the interaction by maintaining lists of workflow and activities tasks, which it dispatches to the respective components. This section describes how the framework works for HelloWorldWorkflow.

HelloWorldWorkflow is implemented by using the AWS Flow Framework for Java API, which handles the sometimes complicated details of interacting with Amazon SWF in the background and simplifies the development process considerably. You can use the same project that you did for HelloWorld, which is already configured for AWS Flow Framework for Java applications. However, to run the application, you must set up an Amazon SWF account, as follows:

- Sign up for an AWS account, if you don't already have one, at Amazon Web Services.
- Assign your account's Access ID and secret ID to the AWS_ACCESS_KEY_ID and AWS_SECRET_KEY environment variables, respectively. It's a good practice to not expose the literal key values in your code. Storing them in environment variables is a convenient way to handle the issue.
- Sign up for Amazon SWF account at Amazon Simple Workflow Service.
- Log into the AWS Management Console and select the Amazon SWF service.
- Click Manage Domains in the upper right corner and register a new Amazon SWF domain. You can use any convenient domain name, but the walkthroughs use "helloWorldExamples".

For more details about how to manage Amazon SWF workflows, see Getting Set Up.

To implement the HelloWorldWorkflow, create a copy of the helloWorld.HelloWorld package in your project folder and name it helloWorld.HelloWorldWorkflow. The following sections describe how to modify the original HelloWorld code to use the AWS Flow Framework for Java and run as an Amazon SWF workflow application.

HelloWorldWorkflow Activities Worker

HelloWorld implemented its activities worker as a single class. An AWS Flow Framework for Java activities worker has three basic components:

- The *activity methods*—which perform the actual tasks—are defined in an interface and implemented in a related class.
- An ActivityWorker class manages the interaction between the activity methods and Amazon SWF.
- An *activities host* application registers and starts the activities worker, and handles cleanup.

This section discusses the activity methods; the other two classes are discussed later.

HelloWorldWorkflow defines the activities interface in `GreeterActivities`, as follows:

```
import com.amazonaws.services.simpleworkflow.flow.annotations.Activities;
import com.amazonaws.services.simpleworkflow.flow.annotations.ActivityRegistra
tionOptions;

@ActivityRegistrationOptions(defaultTaskScheduleToStartTimeoutSeconds = 300,
                             defaultTaskStartToCloseTimeoutSeconds = 10)
@Activities(version="1.0")

public interface GreeterActivities {
 public String getName();
 public String getGreeting(String name);
 public void say(String what);
}
```

This interface wasn't strictly necessary for HelloWorld, but it is for an AWS Flow Framework for Java application. Notice that the interface definition itself hasn't changed. However, you must apply two AWS Flow Framework for Java annotations, @ActivityRegistrationOptions (p. 116) and @Activities (p. 115), to the interface definition. The annotations provide configuration information and direct the AWS Flow Framework for Java annotation processor to use the interface definition to generate an *activities client* class, which is discussed later.

`@ActivityRegistrationOptions` has several named values that are used to configure the activities' behavior. HelloWorldWorkflow specifies two timeouts:

- `defaultTaskScheduleToStartTimeoutSeconds` specifies how long the tasks can be queued in the activities task list, and is set to 300 seconds (5 minutes).
- `defaultTaskStartToCloseTimeoutSeconds` specifies the maximum time the activity can take to perform the task and is set to 10 seconds.

These timeouts ensure that the activity completes its task in a reasonable amount of time. If either timeout is exceeded, the framework generates an error and the workflow worker must decide how to handle the issue. For a discussion of how to handle such error, see Error Handling (p. 84).

`@Activities` has several values, but typically it just specifies the activities' version number, which allows you to keep track of different generations of activity implementations. If you change an activity interface after you have registered it with Amazon SWF, including changing the `@ActivityRegistrationOptions` values, you must use a new version number.

HelloWorldWorkflow implements the activity methods in `GreeterActivitiesImpl`, as follows:

```
public class GreeterActivitiesImpl implements GreeterActivities {
 @Override
 public String getName() {
  return "World";
 }
 @Override
 public String getGreeting(String name) {
  return "Hello " + name;
 }
 @Override
 public void say(String what) {
  System.out.println(what);
 }
}
```

Notice that the code is identical to the HelloWorld implementation. At its core, an AWS Flow Framework activity is just a method that executes some code and perhaps returns a result. The difference between a standard application and an Amazon SWF workflow application lies in how the workflow executes the activities, where the activities execute, and how the results are returned to the workflow worker.

HelloWorldWorkflow Workflow Worker

An Amazon SWF workflow worker has three basic components.

- A *workflow implementation*, which is a class that performs the workflow-related tasks.
- An *activities client* class, which is basically a proxy for the activities class and is used by a workflow implementation to execute activity methods asynchronously.
- A WorkflowWorker class, which manages the interaction between the workflow and Amazon SWF.

This section discusses the workflow implementation and activities client; the WorkflowWorker class is discussed later.

HelloWorldWorkflow defines the workflow interface in `GreeterWorkflow`, as follows:

```
import com.amazonaws.services.simpleworkflow.flow.annotations.Execute;
import com.amazonaws.services.simpleworkflow.flow.annotations.Workflow;
import com.amazonaws.services.simpleworkflow.flow.annotations.WorkflowRegistra
tionOptions;

@Workflow
@WorkflowRegistrationOptions(defaultExecutionStartToCloseTimeoutSeconds = 3600)
public interface GreeterWorkflow {
 @Execute(version = "1.0")
 public void greet();
}
```

This interface also isn't strictly necessary for HelloWorld but is essential for an AWS Flow Framework for Java application. You must apply two AWS Flow Framework for Java annotations, @WorkflowRegistrationOptions (p. 114) and @WorkflowRegistrationOptions (p. 114), to the workflow interface definition. The annotations provide configuration information and also direct the AWS Flow Framework for Java annotation processor to generate a workflow client class based on the interface, as discussed later.

`@Workflow` has one named value, but it is typically used without values to designate `GreeterWorkflow` as a workflow interface. `@WorkflowRegistrationOptions` has several named values that can be used to configure the workflow worker. `HelloWorldWorkflow specifies` one timeout:

- `defaultExecutionStartToCloseTimeoutSeconds` specifies how long the workflow can run and is set to 300 seconds (5 minutes).

The `GreeterWorkflow` interface definition differs from HelloWorld in one important way, the @Execute (p. 114) annotation. Workflow interfaces specify the methods that can be called by applications such as the workflow starter and are limited to a handful of methods, each with a particular role. The framework doesn't specify a name or parameter list for workflow interface methods; you use a name and parameter list that is suitable for your workflow and apply an AWS Flow Framework for Java annotation to identify the method's role.

`@Execute` has two purposes: identifies `greet` as the workflow's entry point—the method that the workflow starter calls to start the workflow. In general, an entry point can take one or more parameters, which allows the starter to initialize the workflow, but this example doesn't require initialization.

- It identifies `greet` as the workflow's entry point—the method that the workflow starter calls to start the workflow. In general, an entry point can take one or more parameters, which allows the starter to initialize the workflow, but this example doesn't require initialization.
- It specifies the workflow's version number, which allows you to keep track of different generations of workflow implementations. To change a workflow interface after you have registered it with Amazon SWF, including changing the timeout values, you must use a new version number.

For information on the other methods that can be included in a workflow interface, see Workflow and Activity Contracts (p. 42).

HelloWorldWorkflow implements the workflow in `GreeterWorkflowImpl`, as follows:

```
import com.amazonaws.services.simpleworkflow.flow.core.Promise;

public class GreeterWorkflowImpl implements GreeterWorkflow {
 private GreeterActivitiesClient operations = new GreeterActivitiesClientImpl();

 public void greet() {
  Promise<String> name = operations.getName();
  Promise<String> greeting = operations.getGreeting(name);
  operations.say(greeting);
 }
}
```

The code is similar to HelloWorld, but with two important differences.

- `GreeterWorkflowImpl` creates an instance of `GreeterActivitiesClientImpl`, the activities client, instead of `GreeterActivitiesImpl`, and executes activities by calling methods on the client object.
- The name and greeting activities return `Promise<String>` objects instead of `String` objects.

HelloWorld is a standard Java application that runs locally as a single process, so `GreeterWorkflowImpl` can implement the workflow topology by simply creating an instance of `GreeterActivitiesImpl`, calling the methods in order, and passing the return values from one activity to the next. With an Amazon SWF workflow, an activity's task is still performed by an activity method from `GreeterActivitiesImpl`. However, the method doesn't necessarily run in the same process as the workflow—it might not even run on the same system—and the workflow needs to execute the activity asynchronously. These requirements raise the following issues:

- How to execute an activity method that might be running in a different process, perhaps on a different system.
- How to execute an activity method asynchronously.
- How to manage activities' input and return values. For example, if the Activity A return value is an input to Activity B, you must ensure that Activity B doesn't execute until Activity A is complete.

You can implement a variety of workflow topologies through the application's control flow by using familiar Java flow control combined with the activities client and the `Promise<T>`.

Activities Client

`GreeterActivitiesClientImpl` is basically a proxy for `GreeterActivitiesImpl` that allows a workflow implementation to execute the `GreeterActivitiesImpl` methods asynchronously.

You don't implement the activities client directly. The AWS Flow Framework for Java annotation processor uses the annotations and code from the `GreeterActivities` interface to generate the `GreeterActivitiesClient` interface and the `GreeterActivitiesClientImpl` class. It creates the class names by simply appending "Client" and "ClientImpl" to the interface name. If you would like to examine the activities client code, Eclipse generates it each time you save the source files and puts the resulting class implementations in the project's `.apt_generated` folder.

A workflow worker executes an activity by calling the corresponding client method. The method is asynchronous and immediately returns a `Promise<T>` object, where `T` is the activity's return type. The returned `Promise<T>` object is basically a placeholder for the value that the activity method will eventually return.

- When the activities client method returns, the `Promise<T>` object is initially in an *unready state*, which indicates that the object does not yet represent a valid return value.
- When the corresponding activity method completes its task and returns, the framework assigns the return value to the `Promise<T>` object and puts it in the *ready state*.

Promise<T> Type

The primary purpose of `Promise<T>` objects is to manage data flow between asynchronous components and control when they execute. It relieves your application of the need to explicitly manage synchronization or depend on mechanisms such as timers to ensure that asynchronous components do not execute prematurely. When you call an activities client method, it immediately returns but the framework defers executing the corresponding activity method until any input `Promise<T>` objects are ready and represent valid data.

From `GreeterWorkflowImpl` perspective, all three activities client methods return immediately. From the `GreeterActivitiesImpl` perspective, the framework doesn't call `getGreeting` until `name` completes, and doesn't call `say` until `getGreeting` completes.

By using `Promise<T>` to pass data from one activity to the next, `HelloWorldWorkflow` not only ensures that activity methods don't attempt to use invalid data, it also controls when the activities execute and implicitly defines the workflow topology. Passing each activity's `Promise<T>` return value to the next activity requires the activities to execute in sequence, defining the linear topology discussed earlier. With AWS Flow Framework for Java, you don't need to use any special modeling code to define even complex topologies, just standard Java flow control and `Promise<T>`. For an example of how to implement a simple parallel topology, see HelloWorldWorkflowParallel Activities Worker (p. 25).

Note
When an activity method such as `say` doesn't return a value, the corresponding client method returns a `Promise<Void>` object. The object doesn't represent data, but it is initially unready and becomes ready when the activity completes. You can therefore pass a `Promise<Void>` object to other activities client methods to ensure that they defer execution until the original activity completes.

`Promise<T>` allows a workflow implementation to use activities client methods and their return values much like synchronous methods. However, you must be careful about accessing a `Promise<T>` object's value. Unlike the Java Future<T> type, the framework handles synchronization for `Promise<T>`, not the application. If you call `Promise<T>.get` and the object is not ready, `get` throws an exception. Notice that `HelloWorldWorkflow` never accesses a `Promise<T>` object directly; it simply passes the objects from one activity to the next. When an object becomes ready, the framework extracts the value and passes it to the activity method as a standard type.

`Promise<T>` objects should be accessed only by asynchronous code, where the framework guarantees that the object is ready and represents a valid value. `HelloWorldWorkflow` deals with this issue by passing `Promise<T>` objects only to activities client methods. You can access a `Promise<T>` object's value in your workflow implementation by passing the object to an *asynchronous workflow method*, which behaves much like an activity. For an example, see HelloWorldWorkflowAsync Application (p. 20).

HelloWorldWorkflow Workflow and Activities Host

The workflow and activities implementations have associated worker classes, ActivityWorker and WorkflowWorker. They handle communication between Amazon SWF and the activities and workflow implementations by polling the appropriate Amazon SWF task list for tasks, executing the appropriate method for each task, and managing the data flow. For details, see Application Structure (p. 28)

To associate the activity and workflow implementations with the corresponding worker objects, you implement one or more worker applications which:

- Register workflows or activities with Amazon SWF.
- Create worker objects and associate them with the workflow or activity worker implementations.
- Direct the worker objects to start communicating with Amazon SWF.

If you want to run the workflow and activities as separate processes, you must implement separate workflow and activities worker hosts. For an example, see HelloWorldWorkflowDistributed Application (p. 23). For simplicity, HelloWorldWorkflow implements a single worker host that runs activities and workflow workers in the same process, as follows:

```
import com.amazonaws.ClientConfiguration;
import com.amazonaws.auth.AWSCredentials;
import com.amazonaws.auth.BasicAWSCredentials;
import com.amazonaws.services.simpleworkflow.AmazonSimpleWorkflow;
import com.amazonaws.services.simpleworkflow.AmazonSimpleWorkflowClient;
import com.amazonaws.services.simpleworkflow.flow.ActivityWorker;
import com.amazonaws.services.simpleworkflow.flow.WorkflowWorker;

public class GreeterWorker  {
 public static void main(String[] args) throws Exception {
  ClientConfiguration config = new ClientConfiguration().withSocket
Timeout(70*1000);

  String swfAccessId = System.getenv("AWS_ACCESS_KEY_ID");
  String swfSecretKey = System.getenv("AWS_SECRET_KEY");
  AWSCredentials awsCredentials = new BasicAWSCredentials(swfAccessId, swf
SecretKey);

  AmazonSimpleWorkflow service = new AmazonSimpleWorkflowClient(awsCredentials,
 config);
  service.setEndpoint("https://swf.us-east-1.amazonaws.com");

  String domain = " helloWorldExamples";
  String taskListToPoll = "HelloWorldList";

  ActivityWorker aw = new ActivityWorker(service, domain, taskListToPoll);
  aw.addActivitiesImplementation(new GreeterActivitiesImpl());
  aw.start();

  WorkflowWorker wfw = new WorkflowWorker(service, domain, taskListToPoll);
  wfw.addWorkflowImplementationType(GreeterWorkflowImpl.class);
  wfw.start();
 }
}
```

`GreeterWorker` has no HelloWorld counterpart, so you must add a Java class named `GreeterWorker` to the project and copy the example code to that file.

The first step is to create and configure an AmazonSimpleWorkflowClient object, which invokes the underlying Amazon SWF service methods. To do so, `GreeterWorker`:

1. Creates a ClientConfiguration object and specifies a socket timeout of 70 seconds. This value specifies long to wait for data to be transferred over an established open connection before closing the socket.
2. Creates a BasicAWSCredentials object to identify the Amazon AWS account and passes the account keys to the constructor. For convenience, and to avoid exposing them as plain text in the code, the keys are stored as environment variables.

3. Creates an AmazonSimpleWorkflowClient object to represent the workflow, and passes the AmazonSimpleWorkflowConfig object and access keys to the constructor.
4. Sets the client object's service endpoint URL. Currently, only US East (Northern Virginia) Region supports Amazon SWF.

For convenience, `GreeterWorker` defines two string constants.

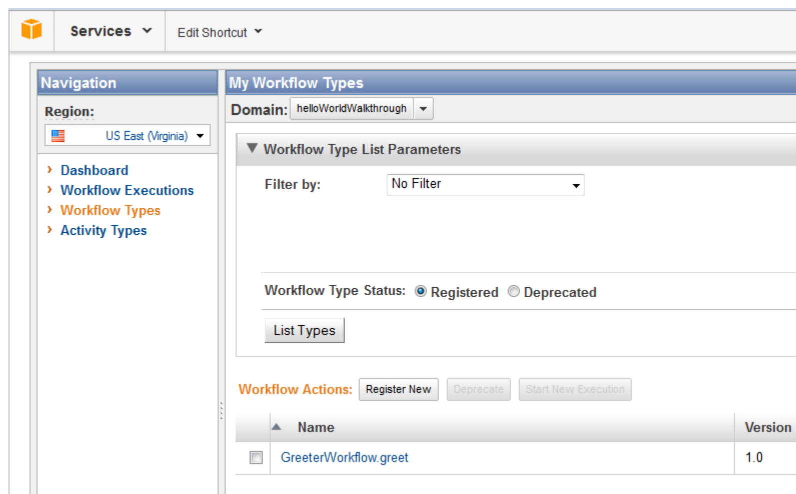
- `domain` is the workflow's Amazon SWF domain name, which you created when you set up your Amazon SWF account. `HelloWorldWorkflow` assumes that you are running the workflow in the "helloWorldExamples" domain.
- `taskListToPoll` is the name of the task lists that Amazon SWF uses to manage communication between the workflow and activities workers. You can set the name to any convenient string. HelloWorldWorkflow uses "HelloWorldList" for both workflow and activity task lists. Behind the scenes, the names end up in different namespaces, so the two task lists are distinct.

`GreeterWorker` uses the string constants and the AmazonSimpleWorkflowClient object to create worker objects, which manage the interaction between the activities and worker implementations and Amazon SWF. In particular, the worker objects handle the task of polling the appropriate task list for tasks.

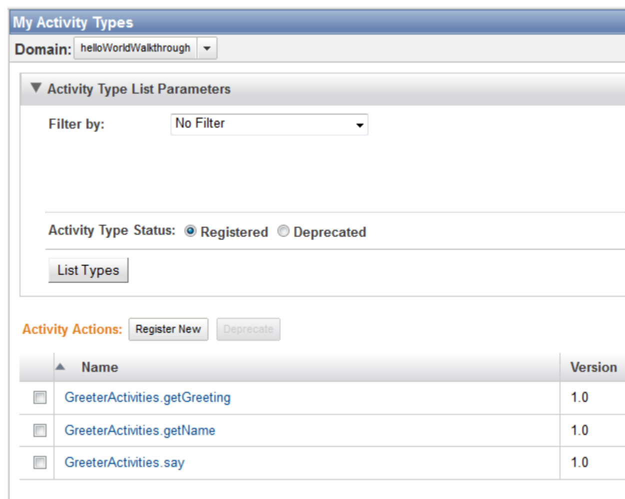
`GreeterWorker` creates an `ActivityWorker` object and configures it to handle `GreeterActivitiesImpl` by adding a new class instance. `GreeterWorker` then calls the `ActivityWorker` object's `start` method, which directs the object to start polling the specified activities task list.

`GreeterWorker` creates a `WorkflowWorker` object and configures it to handle `GreeterWorkflowImpl` by adding the class file name, `GreeterWorkflowImpl.class`. It then calls the `WorkflowWorker` object's `start` method, which directs the object to start polling the specified workflow task list.

You can run `GreeterWorker` successfully at this point. It registers the workflow and activities with Amazon SWF and starts the worker objects polling their respective task lists. To verify this, run `GreeterWorker` and go to the Amazon SWF console and selecting `helloWorldWalkthrough` from the list of domains. If you click **Workflow Types** in the **Navigation** pane, you should see `GreeterWorkflow.greet`, as shown in the following screen shot.



If you click **Activity Types**, you should see the `GreeterActivities` methods, as shown in the following screen shot.



However, if you click **Workflow Executions**, you will not see any active executions. The workflow and activities workers are polling for tasks, but Amazon SWF hasn't started managing the task lists yet.

HelloWorldWorkflow Starter

The final piece of the puzzle is to implement a workflow starter, which is an application that starts up the Amazon SWF side of the whole process. HelloWorldWorkflow implements a workflow starter by modifying the `GreeterMain` class, as follows:

```
import com.amazonaws.ClientConfiguration;
import com.amazonaws.auth.AWSCredentials;
import com.amazonaws.auth.BasicAWSCredentials;
import com.amazonaws.services.simpleworkflow.AmazonSimpleWorkflow;
import com.amazonaws.services.simpleworkflow.AmazonSimpleWorkflowClient;

public class GreeterMain {

 public static void main(String[] args) throws Exception {
  ClientConfiguration config = new ClientConfiguration().withSocket
Timeout(70*1000);

  String swfAccessId = System.getenv("AWS_ACCESS_KEY_ID");
  String swfSecretKey = System.getenv("AWS_SECRET_KEY");
  AWSCredentials awsCredentials = new BasicAWSCredentials(swfAccessId, swf
SecretKey);

  AmazonSimpleWorkflow service = new AmazonSimpleWorkflowClient(awsCredentials,
 config);
  service.setEndpoint("https://swf.us-east-1.amazonaws.com");

  String domain = "helloWorldWalkthrough";

  GreeterWorkflowClientExternalFactory factory = new GreeterWorkflowClientEx
ternalFactoryImpl(service, domain);
  GreeterWorkflowClientExternal greeter = factory.getClient("someID");
  greeter.greet();
 }
}
```

GreeterMain creates an AmazonSimpleWorkflowClient object by using the same code as GreeterWorker. It then creates a GreeterWorkflowClientExternal object, which acts as a proxy for the workflow in much the same way that the activities client created in GreeterWorkflowClientImpl acts as a proxy for the activity methods. Rather than create a workflow client object by using new, you must:

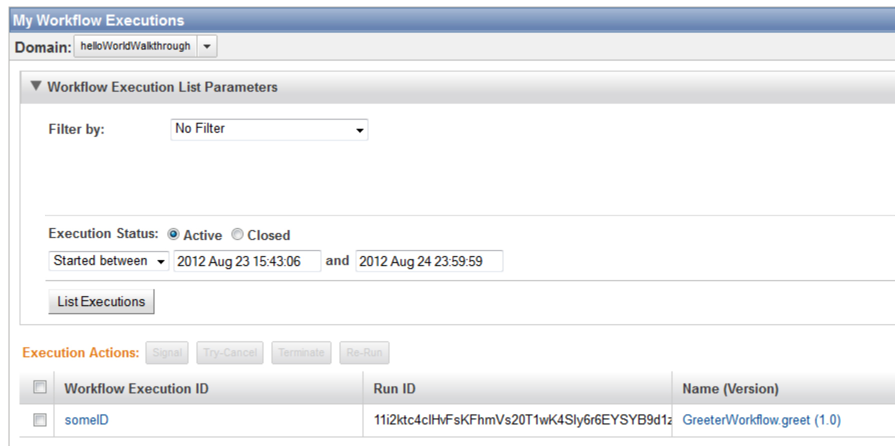
1. Create an external client factory object and pass the AmazonSimpleWorkflowClient object and Amazon SWF domain name to the constructor. The client factory object is created by the framework's annotation processor, which creates the object name by simply appending "ClientExternalFactoryImpl" to the workflow interface name.
2. Create an external client object by calling the factory object's getClient method, which creates the object name by appending "ClientExternal" to the workflow interface name. You can optionally pass getClient a string which Amazon SWF will use to identify this instance of the workflow. Otherwise, Amazon SWF represents a workflow instance by using a generated GUID.

The workflow client exposes a greet method that GreeterMain calls to direct Amazon SWF to start managing the task lists.

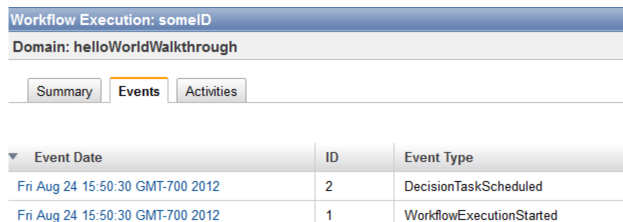
Note

The annotation processor also creates an internal client factory object that is used to create child workflows. For details, see Child Workflow Executions (p. 69).

Shut down GreeterWorker for the moment if it is still running, and run GreeterMain. You should now see someID on the Amazon SWF console's list of active workflow executions, as shown in the following screenshot.



If you click someID and click the **Events** tab, you should see events shown in the following screen shot.



Note

If you started GreeterWorker earlier, and it is still running, you will see a longer event list for reasons discussed shortly. Stop GreeterWorker and try running GreaterMain again.

The **Events** tab shows only two events:

- `WorkflowExecutionStarted` indicates that the workflow has started executing.
- `DecisionTaskScheduled` indicates that Amazon SWF has queued the first decision task.

The reason that the workflow is blocked at the first decision task is that the workflow is distributed across two applications, `GreeterMain` and `GreeterWorker`. `GreeterMain` directed Amazon SWF to start managing the task lists but `GreeterWorker` is not running, so the workers aren't polling the lists and executing tasks. You can run either application independently, but you need both for workflow execution to proceed beyond the first decision task. If you now run `GreeterWorker`, the workflow and activity workers will start polling and the various tasks will be completed rapidly. If you now check the `Events` tab, you should see something like the following screen shot, which shows the first eleven events.

Workflow Execution: someID
Domain: helloWorldWalkthrough

Summary | Events | Activities

Event Date	ID	Event Type
Fri Aug 24 15:50:30 GMT-700 2012	1	WorkflowExecutionStarted
Fri Aug 24 15:50:30 GMT-700 2012	2	DecisionTaskScheduled
Fri Aug 24 15:52:19 GMT-700 2012	3	DecisionTaskStarted
Fri Aug 24 15:52:19 GMT-700 2012	4	DecisionTaskCompleted
Fri Aug 24 15:52:19 GMT-700 2012	5	ActivityTaskScheduled
Fri Aug 24 15:52:20 GMT-700 2012	6	ActivityTaskStarted
Fri Aug 24 15:52:20 GMT-700 2012	7	ActivityTaskCompleted
Fri Aug 24 15:52:20 GMT-700 2012	8	DecisionTaskScheduled
Fri Aug 24 15:52:20 GMT-700 2012	9	DecisionTaskStarted
Fri Aug 24 15:52:20 GMT-700 2012	10	DecisionTaskCompleted
Fri Aug 24 15:52:20 GMT-700 2012	11	ActivityTaskScheduled

You can click individual events to get more information. By the time you've finished looking, the workflow should have printed "Hello World!" to your console.

After the workflow completes, it no longer appears on the list of active executions. However, if you want to review it, click the **Closed** execution status button and click **List Executions**. This displays all the completed workflow instances in the specified domain that have not exceeded their retention time, which you specified when you created the domain.

The following screen shot shows a list of completed workflows in the helloWorldWalkthrough domain.

Notice that each workflow instance has a unique **Run ID** value. You can use the same Execution ID for different workflow instances, but only for one active execution at a time.

HelloWorldWorkflowAsync Application

Sometimes, it's preferable to have a workflow perform certain tasks locally instead of using activity. However, workflow tasks often involve processing the values represented by `Promise<T>` objects. If you pass a `Promise<T>` object to a synchronous workflow method, the method executes immediately but it can't access the `Promise<T>` object's value until the object is ready. You could poll `Promise<T>.isReady` until it returns `true`, but that's inefficient and the method might block for a long time. A better approach is to use an *asynchronous method*.

An asynchronous method is implemented much like a standard method—often as a member of the workflow implementation class—and runs in the workflow implementation's context. You designate it as an asynchronous method by applying an `@Asynchronous` annotation, which directs the framework to treat it much like an activity.

- When a workflow implementation calls an asynchronous method, it returns immediately. Asynchronous methods typically return a `Promise<T>` object, which becomes ready when the method completes.
- If you pass an asynchronous method one or more `Promise<T>` objects, it defers execution until all the input objects are ready. An asynchronous method can therefore access its input `Promise<T>` values without risking an exception.

Note

Because of the way that the AWS Flow Framework for Java executes the workflow, asynchronous methods typically execute multiple times, so you should use them only for quick low-overhead tasks. You should use activities to perform lengthy tasks such as large computations. For details, see AWS Flow Framework Basic Concepts: Distributed Execution (p. 32).

This topic is a walkthrough of HelloWorldWorkflowAsync, a modified version of HelloWorldWorkflow that replaces one of the activities with an asynchronous method. To implement the application, create a copy of the helloWorld.HelloWorldWorkflow package in your project folder and name it helloWorld.HelloWorldWorkflowAsync. The following sections describe how to modify the original HelloWorldWorkflow code to use an asynchronous method.

HelloWorldWorkflowAsync Activities Implementation

HelloWorldWorkflowAsync implements its activities worker interface in `GreeterActivities`, as follows:

```
import com.amazonaws.services.simpleworkflow.flow.annotations.Activities;
import com.amazonaws.services.simpleworkflow.flow.annotations.ActivityRegistra
tionOptions;

@Activities(version="2.0")
@ActivityRegistrationOptions(defaultTaskScheduleToStartTimeoutSeconds = 300,
                             defaultTaskStartToCloseTimeoutSeconds = 10)
public interface GreeterActivities {
 public String getName();
 public void say(String what);
}
```

This interface is similar to the one used by HelloWorldWorkflow, with the following exceptions:

- It omits the `getGreeting` activity; that task is now handled by an asynchronous method.
- The version number is set to 2.0. After you have registered an activities interface with Amazon SWF, you can't modify it unless you change the version number.

The remaining activity method implementations are identical to HelloWorldWorkflow. Just delete `getGreeting` from `GreeterActivitiesImpl`.

HelloWorldWorkflowAsync Workflow Implementation

HelloWorldWorkflowAsync defines the workflow interface as follows:

```
import com.amazonaws.services.simpleworkflow.flow.annotations.Execute;
import com.amazonaws.services.simpleworkflow.flow.annotations.Workflow;
import com.amazonaws.services.simpleworkflow.flow.annotations.WorkflowRegistra
tionOptions;

@Workflow
@WorkflowRegistrationOptions(defaultExecutionStartToCloseTimeoutSeconds = 3600)
public interface GreeterWorkflow {

 @Execute(version = "2.0")
 public void greet();
}
```

The interface is identical to HelloWorldWorkflow apart from a new version number. As with activities, if you want to change a registered workflow, you must change its version number.

HelloWorldWorkflowAsync implements the workflow as follows:

```
import com.amazonaws.services.simpleworkflow.flow.annotations.Asynchronous;
import com.amazonaws.services.simpleworkflow.flow.core.Promise;
```

```
public class GreeterWorkflowImpl implements GreeterWorkflow {
 private GreeterActivitiesClient operations = new GreeterActivitiesClientImpl();

 @Override
 public void greet() {
  Promise<String> name = operations.getName();
  Promise<String> greeting = getGreeting(name);
  operations.say(greeting);
 }

 @Asynchronous
 private Promise<String> getGreeting(Promise<String&gt; name) {
  String returnString = "Hello " + name.get() + "!";
  return Promise.asPromise(returnString);
 }
}
```

HelloWorldWorkflowAsync replaces the `getGreeting` activity with a `getGreeting` asynchronous method but the `greet` method works in much the same way:

1. Execute the `getName` activity, which immediately returns a `Promise<String>` object, `name`, that represents the name.
2. Call the `getGreeting` asynchronous method and pass it the `name` object. `getGreeting` immediately returns a `Promise<String>` object, `greeting`, that represents the greeting.
3. Execute the `say` activity and pass it the `greeting` object.
4. When `getName` completes, `name` becomes ready and `getGreeting` uses its value to construct the greeting.
5. When `getGreeting` completes, `greeting` becomes ready and `say` prints the string to the console.

The difference is that, instead of calling the activities client to execute a `getGreeting` activity, greet calls the asynchronous `getGreeting` method. The net result is the same, but the `getGreeting` method works somewhat differently than the `getGreeting` activity.

- The workflow worker uses a standard function call to execute `getGreeting`; the interaction is not mediated by Amazon SWF.
- `getGreeting` runs in the workflow implementation's process.
- `getGreeting` returns a `Promise<String>` object rather than a `String` object. When you execute an activity, you call a method on the activities client, which returns a `Promise<T>` object. The activity method returns a standard type, which the framework then assigns to the `Promise<T>`. Because the workflow calls `getGreeting` directly, it must explicitly return a `Promise<T>` type.

`getGreeting` creates a return value by passing the greeting string to the static `Promise.asPromise` method. This method creates a `Promise<T>` object of the appropriate type, sets the value, and puts it in the ready state.

HelloWorldWorkflowAsync Workflow and Activities Host and Starter

HelloWorldWorkflowAsync implements `GreeterWorker` as the host class for the workflow and activity implementations. It is identical to the HelloWorldWorkflow implementation except for the `taskListToPoll` name, which is set to "`HelloWorldAsyncList`".

HelloWorldWorkflowAsync implements the workflow starter in `GreeterMain`, and it is identical to the HelloWorldWorkflow implementation.

To execute the workflow, run `GreeterWorker` and `GreeterMain`, just as with HelloWorldWorkflow.

HelloWorldWorkflowDistributed Application

With HelloWorldWorkflow and HelloWorldWorkflowAsync, Amazon SWF mediates the interaction between the workflow and activities implementations, but they run locally as a single process. `GreeterMain` is in a separate process, but it still runs on the same system.

A key feature of Amazon SWF is that it supports distributed applications. For example, you could run the workflow worker on an EC2 instance, the workflow starter on a data center computer, and the activities on a client desktop computer. You can even run different activities on different systems.

The HelloWorldWorkflowDistributed application extends HelloWorldWorkflowAsync to distribute the application across two systems and three processes.

- The workflow and workflow starter run as separate processes on one system.
- The activities run on a separate system.

To implement the application, create a copy of the helloWorld.HelloWorldWorkflowAsync package in your project folder and name it helloWorld.HelloWorldWorkflowDistributed. The following sections describe how to modify the original HelloWorldWorkflowAsync code to distribute the application across two systems and three processes.

You don't need to change the workflow or activities implementations to run them on separate systems, not even the version numbers. You also don't need to modify `GreeterMain`. All you need to change is the activities and workflow host.

With HelloWorldWorkflowAsync, a single application serves as the workflow and activity host. To run the workflow and activity implementations on separate systems, you must implement separate applications. Delete GreeterWorker from the project and add two new class files, GreeterWorkflowWorker and GreeterActivitiesWorker.

HelloWorldWorkflowDistributed implements its activities host in GreeterActivitiesWorker, as follows:

```
 import com.amazonaws.ClientConfiguration;
import com.amazonaws.auth.AWSCredentials;
import com.amazonaws.auth.BasicAWSCredentials;
import com.amazonaws.services.simpleworkflow.AmazonSimpleWorkflow;
import com.amazonaws.services.simpleworkflow.AmazonSimpleWorkflowClient;
import com.amazonaws.services.simpleworkflow.flow.ActivityWorker;

public class GreeterActivitiesWorker {
 public static void main(String[] args) throws Exception {
  ClientConfiguration config = new ClientConfiguration().withSocket
Timeout(70*1000);

  String swfAccessId = System.getenv("AWS_ACCESS_KEY_ID");
  String swfSecretKey = System.getenv("AWS_SECRET_KEY");
  AWSCredentials awsCredentials = new BasicAWSCredentials(swfAccessId, swf
SecretKey);
```

```
  AmazonSimpleWorkflow service = new AmazonSimpleWorkflowClient(awsCredentials,
 config);
  service.setEndpoint("https://swf.us-east-1.amazonaws.com");

  String domain = "helloWorldExamples";
  String taskListToPoll = "HelloWorldAsyncList";

  ActivityWorker aw = new ActivityWorker(service, domain, taskListToPoll);
  aw.addActivitiesImplementation(new GreeterActivitiesImpl());
  aw.start();
 }
}
```

HelloWorldWorkflowDistributed implements its workflow host in `GreeterWorkflowWorker`, as follows:

```
import com.amazonaws.ClientConfiguration;
import com.amazonaws.auth.AWSCredentials;
import com.amazonaws.auth.BasicAWSCredentials;
import com.amazonaws.services.simpleworkflow.AmazonSimpleWorkflow;
import com.amazonaws.services.simpleworkflow.AmazonSimpleWorkflowClient;
import com.amazonaws.services.simpleworkflow.flow.WorkflowWorker;

public class GreeterWorkflowWorker {
 public static void main(String[] args) throws Exception  {
  ClientConfiguration config = new ClientConfiguration().withSocket
Timeout(70*1000);

  String swfAccessId = System.getenv("AWS_ACCESS_KEY_ID");
  String swfSecretKey = System.getenv("AWS_SECRET_KEY");
  AWSCredentials awsCredentials = new BasicAWSCredentials(swfAccessId, swf
SecretKey);

  AmazonSimpleWorkflow service = new AmazonSimpleWorkflowClient(awsCredentials,
 config);
  service.setEndpoint("https://swf.us-east-1.amazonaws.com");

  String domain = "helloWorldExamples";
  String taskListToPoll = "HelloWorldAsyncList";

  WorkflowWorker wfw = new WorkflowWorker(service, domain, taskListToPoll);
  wfw.addWorkflowImplementationType(GreeterWorkflowImpl.class);
  wfw.start();
 }
}
```

Note that `GreeterActivitiesWorker` is just `GreeterWorker` without the `WorkflowWorker` code and `GreeterWorkflowWorker` is just `GreeterWorker` without the `ActivityWorker` code.

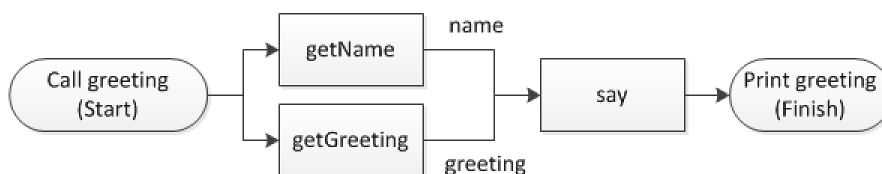
To run the workflow:

1. Create a runnable JAR file with `GreeterActivitiesWorker` as the entry point.
2. Copy the JAR file from Step 1 to another system, which can be running any operating system that supports Java.
3. Run the JAR file.
4. On your development system, use Eclipse to run `GreeterWorkflowWorker` and `GreeterMain`.

Other than the fact that the activities are running on a different system than the workflow worker and workflow starter, the workflow works in exactly the same way as HelloWorldAsync. However, because `println` call that prints "Hello World!" to the console is in the `say` activity, the output will appear on the system that is running the activities worker.

HelloWorldWorkflowParallel Application

The preceding versions of Hello World! all use a linear workflow topology. However, Amazon SWF is not limited to linear topologies. The HelloWorldWorkflowParallel application is a modified version of HelloWorldWorkflow that uses a parallel topology, as shown in the following figure.



With HelloWorldWorkflowParallel, `getName` and `getGreeting` run in parallel and each return part of the greeting. `say` then merges the two strings into a greeting, and prints it to the console.

To implement the application, create a copy of the helloWorld.HelloWorldWorkflow package in your project folder and name it helloWorld.HelloWorldWorkflowParallel. The following sections describe how to modify the original HelloWorldWorkflow code to run `getName` and `getGreeting` in parallel.

HelloWorldWorkflowParallel Activities Worker

The HelloWorldWorkflowParallel activities interface is implemented in `GreeterActivities`, as shown in the following example.

```
import com.amazonaws.services.simpleworkflow.flow.annotations.Activities;
import com.amazonaws.services.simpleworkflow.flow.annotations.ActivityRegistra
tionOptions;

@Activities(version="5.0")
@ActivityRegistrationOptions(defaultTaskScheduleToStartTimeoutSeconds = 300,
                             defaultTaskStartToCloseTimeoutSeconds = 10)
public interface GreeterActivities {
 public String getName();
 public String getGreeting();
 public void say(String greeting, String name);
}
```

The interface is similar to HelloWorldWorkflow, with the following exceptions:

- `getGreeting` does not take any input; it simply returns a greeting string.
- `say` takes two input strings, the greeting and the name.
- The interface has a new version number, which is required any time that you change a registered interface.

HelloWorldWorkflowParallel implements the activities in `GreeterActivitiesImpl`, as follows:

```
public class GreeterActivitiesImpl implements GreeterActivities {

 @Override
 public String getName() {
  return "World!";
 }

 @Override
 public String getGreeting() {
  return "Hello ";
 }

 @Override
 public void say(String greeting, String name) {
  System.out.println(greeting + name);
 }
}
```

`getName` and `getGreeting` now simply return half of the greeting string. `say` concatenates the two pieces to produce the complete phrase, and prints it to the console.

HelloWorldWorkflowParallel Workflow Worker

The HelloWorldWorkflowParallel workflow interface is implemented in `GreeterWorkflow`, as follows:

```
import com.amazonaws.services.simpleworkflow.flow.annotations.Execute;
import com.amazonaws.services.simpleworkflow.flow.annotations.Workflow;
import com.amazonaws.services.simpleworkflow.flow.annotations.WorkflowRegistra
tionOptions;

@Workflow
@WorkflowRegistrationOptions(defaultExecutionStartToCloseTimeoutSeconds = 3600)
public interface GreeterWorkflow {

 @Execute(version = "5.0")
 public void greet();
}
```

The class is identical to the HelloWorldWorkflow version, except that the version number has been changed to match the activities worker.

The workflow is implemented in `GreeterWorkflowwImpl`, as follows:

```
import com.amazonaws.services.simpleworkflow.flow.core.Promise;

public class GreeterWorkflowImpl implements GreeterWorkflow {
 private GreeterActivitiesClient operations = new GreeterActivitiesClientImpl();

 public void greet() {
  Promise<String> name = operations.getName();
  Promise<String> greeting = operations.getGreeting();
  operations.say(greeting, name);
```

```
  }
}
```

At a glance, this implementation looks very similar to HelloWorldWorkflow; the three activities client methods execute in sequence. However, the activities do not.

- HelloWorldWorkflow passed `name` to `getGreeting`. Because `name` was a `Promise<T>` object, `getGreeting` deferred executing the activity until `getName` completed, so the two activities executed in sequence.
- HelloWorldWorkflowParallel doesn't pass any input `getName` or `getGreeting`. Neither method defers execution and the associated activity methods execute immediately, in parallel.

The `say` activity takes both `greeting` and `name` as input parameters. Because they are `Promise<T>` objects, `say` defers execution until both activities complete, and then constructs and prints the greeting.

Notice that HelloWorldWorkflowParallel doesn't use any special modelling code to define the workflow topology. It does it implicitly by using standard Java flow control and taking advantage of the properties of `Promise<T>` objects. AWS Flow Framework for Java applications can implement even complex topologies simply by using `Promise<T>` objects in conjunction with conventional Java control flow constructs.

HelloWorldWorkflowParallel Workflow and Activities Host and Starter

HelloWorldWorkflowParallel implements `GreeterWorker` as the host class for the workflow and activity implementations. It is identical to the HelloWorldWorkflow implementation except for the `taskListToPoll` name, which is set to "HelloWorldParallelList".

`HelloWorldWorkflowParallel` implements the workflow starter in `GreeterMain`, and it is identical to the HelloWorldWorkflow implementation.

To execute the workflow, run `GreeterWorker` and `GreeterMain`, just as with `HelloWorldWorkflow`.

AWS Flow Framework for Java Basic Concepts

The AWS Flow Framework for Java works with Amazon SWF to make it easy to create scalable and fault-tolerant applications to perform asynchronous tasks that may be long running, remote, or both. The "Hello World!" examples in Introduction (p. 1) introduced the basics of how to use the AWS Flow Framework to implement basic workflow applications. This section provides conceptual information about how AWS Flow Framework applications work. The first section summarizes the basic structure of an AWS Flow Framework application, and the remaining sections provide further detail about how AWS Flow Framework applications work.

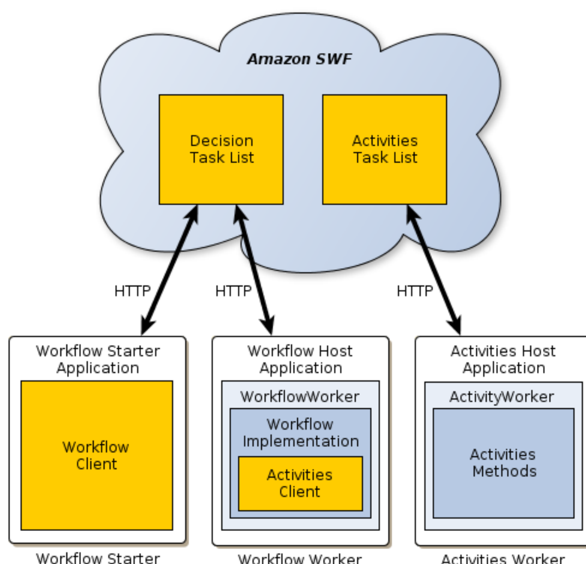
AWS Flow Framework Basic Concepts: Application Structure

Conceptually, an AWS Flow Framework application consists of three basic components: a *workflow starter*, a *workflow worker*, and an *activities worker*. The host application is responsible for registering the workers with Amazon SWF, starting the workers, and handling cleanup. The workers, usually embedded in the host applications, handle the mechanics of executing the workflow.

This diagram represents a basic AWS Flow Framework application:



Note

Implementing these components as three separate applications is convenient conceptually, but applications can implement their functionality in a variety of ways. For example, you can use a single host application for the activity and workflow workers, or use separate activity and workflow hosts. You can also have multiple activity workers, each handling different set of activities with separate hosts, and so on.

The three AWS Flow Framework components interact indirectly by sending HTTP requests to Amazon SWF, which manages the requests. Amazon SWF does the following:

- Maintains one or more decision task lists, which queue tasks to be performed by the workflow worker, such as executing an activity.
- Maintains one or more activities task lists, which queue tasks to be performed by the activities worker.
- Maintains a detailed step-by-step history of the workflow's execution.

With the AWS Flow Framework, your application code does not need to deal directly with many of the details shown in the figure, such as sending HTTP requests to Amazon SWF. You simply call AWS Flow Framework methods and the framework handles the details behind the scenes.

Role of the Activities Worker

The activities worker performs the various tasks that the workflow must accomplish. It consists of:

- The activities implementation, which includes of a set of activity methods that perform particular tasks for the workflow.
- An activity worker, which uses HTTP long poll requests to poll Amazon SWF for activity tasks. When a task is available, Amazon SWF responds to the request by sending the information required to perform the task. The activity worker then calls the appropriate activity method, and returns the results to Amazon SWF.

Role of the Workflow Worker

The workflow worker orchestrates the execution of the various activities, manages data flow, and handles failed activities. It consists of:

- The workflow implementation, which includes the activity orchestration logic, handles failed activities, and so on.
- An activities client, which serves as a proxy for the activities worker and enables the workflow worker to schedule activities to be executed asynchronously.
- A workflow worker object, which uses HTTP long poll requests to poll Amazon SWF for decision tasks. If there are tasks on the workflow task list, Amazon SWF responds to the request by returning the information that is required to perform the task. The framework then executes the workflow to perform the task and returns the results to Amazon SWF.

Role of the Workflow Starter

The workflow starter starts a workflow instance, also referred to as a *workflow execution*, and can interact with an instance during execution for purposes such as passing additional data to the workflow worker or obtaining the current workflow state.

The workflow starter uses a workflow client to start the workflow execution, interacts with the workflow as needed during execution, and handles cleanup. The workflow starter could be a locally-run application, a web application, the AWS CLI or even the AWS Management Console.

How Amazon SWF Interacts with Your Application

Amazon SWF mediates the interaction between the workflow components and maintains a detailed workflow history. Amazon SWF does not initiate communication with the components; it waits for HTTP requests from the components and manages the requests as required. For example:

- If the request is from a worker, polling for available tasks, Amazon SWF responds directly to the worker if a task is available. For more information on how polling works, see Polling for Tasks in the *Amazon Simple Workflow Service Developer Guide*.
- If the request is a notification from an activity worker that a task is complete, Amazon SWF records the information in the execution history and adds a task to the decision task list to inform the workflow worker that the task is complete, allowing it to proceed to the next step.
- If the request is from the workflow worker to execute an activity, Amazon SWF records the information in the execution history and adds a task to the activities task list to direct an activity worker to execute the appropriate activity method.

This approach allows workers to run on any system with an Internet connection, including Amazon EC2 instances, corporate data centers, client computers, and so on. They don't even have to be running the same operating system. Because the HTTP requests originate with the workers, there is no need for externally visible ports; workers can run behind a firewall.

For More Information

For a more thorough discussion of how Amazon SWF works, see Amazon Simple Workflow Service Developer Guide.

AWS Flow Framework Basic Concepts: Reliable Execution

Asynchronous distributed applications must deal with reliability issues that are not encountered by conventional applications, including:

- How to *provide reliable communication* between asynchronous distributed components, such as long-running components on remote systems.
- How to *ensure that results are not lost* if a component fails or is disconnected, especially for long-running applications.
- How to *handle failed distributed components*.

Applications can rely on the AWS Flow Framework and Amazon SWF to manage these issues. We'll explore how Amazon SWF provides mechanisms to ensure that your workflows operate reliably and in a predictable way, even when they are long-running and depend on asynchronous tasks carried out computationally and with human interaction.

Providing Reliable Communication

AWS Flow Framework provides reliable communication between a workflow worker and its activities workers by using Amazon SWF to dispatch tasks to distributed activities workers and return the results to the workflow worker. Amazon SWF uses the following methods to ensure reliable communication between a worker and its activities:

- Amazon SWF durably stores scheduled activity and workflow tasks and guarantees that they will be performed at most once.
- Amazon SWF guarantees that an activity task will either complete successfully and return a valid result or it will notify the workflow worker that the task failed.
- Amazon SWF durably stores each completed activity's result or, for failed activities, it stores relevant error information.

The AWS Flow Framework then uses the activity results from Amazon SWF to determine how to proceed with the workflow's execution.

Ensuring that Results are Not Lost

Maintaining Workflow History

An activity that performs a data-mining operation on a petabyte of data might take *hours* to complete, and an activity that directs a human worker to perform a complex task might take *days*, or even *weeks* to complete!

To accommodate scenarios such as these, AWS Flow Framework workflows and activities can take arbitrarily long to complete: *up to a limit of one year* for a workflow execution. Reliably executing long running processes requires a mechanism to durably store the workflow's execution history on an ongoing basis.

The AWS Flow Framework handles this by depending on Amazon SWF, which maintains a running history of each workflow instance. The workflow's history provides a complete and authoritative record of the workflow's progress, including all the workflow and activity tasks that have been scheduled and completed, and the information returned by completed or failed activities.

AWS Flow Framework applications usually do not need to interact with the workflow history directly, although they can access it if necessary. For most purposes, applications can simply let the framework interact with the workflow history behind the scenes. For a full discussion of workflow history, see Workflow History in the *Amazon Simple Workflow Service Developer Guide*.

Stateless Execution

The execution history allows workflow workers to be *stateless*. If you have multiple instances of a workflow or activity worker, any worker can perform any task. The worker receives all the state information that it needs to perform the task from Amazon SWF.

This approach makes workflows more reliable. For example, if an activity worker fails, you don't have to restart the workflow. Just restart the worker and it will start polling the task list and processing whatever tasks are on the list, regardless of when the failure occurred. You can make your overall workflow fault-tolerant by using two or more workflow and activity workers, perhaps on separate systems. Then, if one of the workers fails, the others will continue to handle scheduled tasks without any interruption in workflow progress.

Handling Failed Distributed Components

Activities often fail for ephemeral reasons, such as a brief disconnection, so a common strategy for handling failed activities is to retry the activity. Instead of handling the retry process by implementing complex message passing strategies, applications can depend on the AWS Flow Framework. It provides several mechanisms for retrying failed activities, and provides a built-in exception-handling mechanism that works with asynchronous, distributed execution of tasks in a workflow.

AWS Flow Framework Basic Concepts: Distributed Execution

A workflow instance is essentially a virtual thread of execution that can span activities and orchestration logic running on multiple remote computers. Amazon SWF and the AWS Flow Framework function as an operating system that manages workflow instances on a virtual CPU by:

- Maintaining each instance's execution state.
- Switching between instances.
- Resuming execution of a instance at the point that it was switched out.

Replaying Workflows

Because activities can be long-running, it's inefficient to have the workflow simply block until they complete. Instead, the AWS Flow Framework manages workflow execution by using a *replay* mechanism, which relies on the workflow history maintained by Amazon SWF to execute the workflow in episodes. Each episode replays the workflow logic, but does so in a way that executes each activity only once, and ensures that activities and asynchronous methods don't execute until their Promise (p. 36) objects are ready.

The workflow starter initiates the first replay episode when it starts the workflow execution. The framework calls the workflow's entry point method and:

- Executes all workflow tasks that do not depend on activity completion, including calling all activity client methods.

- Gives Amazon SWF a list of activities tasks to be scheduled for execution. For the first episode, this list consists of only those activities that do not depend on a Promise and can be executed immediately.
- Notifies Amazon SWF that the episode is complete.

Amazon SWF stores the activity tasks in the workflow history and schedules them for execution by placing them on the activity task list. The activity workers poll the task list and execute the tasks.

When an activity worker completes a task, it returns the result to Amazon SWF, which records it in the workflow execution history and schedules a new *workflow task* for the workflow worker by placing it on the workflow task list. The workflow worker polls the task list and when it receives the task, it runs the next replay episode, as follows:

1. The framework runs the workflow's entry point method again and:
   - Executes all workflow tasks that do not depend on activity completion, including calling all activity client methods. However, the framework checks the execution history and does not schedule duplicate activity tasks.
   - Checks the history to see which activity tasks have completed and executes any asynchronous workflow methods that depend on those activities.
2. When all workflow tasks that can be executed have completed, the framework reports back to Amazon SWF:
   - It gives Amazon SWF a list of any activities whose input `Promise<T>` objects have become ready since the last episode and can be scheduled for execution.
   - If the episode generated no additional activity tasks but there are still uncompleted activities, the framework notifies Amazon SWF that the episode is complete. It then waits for another activity to complete, initiating the next replay episode.
   - If the episode generated no additional activity tasks and all activities have completed, the framework notifies Amazon SWF that the workflow execution is complete.

For examples of replay behavior, see Replay Behavior (p. 101).

Replay and Asynchronous Workflow Methods

Asynchronous workflow methods are often used much like activities, because the method defers execution until all input `Promise<T>` objects are ready. However, the replay mechanism handles asynchronous methods differently than activities.

- Replay does not guarantee that an asynchronous method will execute only once. It defers execution on an asynchronous method until its input Promise objects are ready, but it then executes that method for all subsequent episodes.
- When an asynchronous method completes, it does not start a new episode.

An example of replaying an asynchronous workflow is provided in Replay Behavior (p. 101).

Replay and Workflow Implementation

For the most part, you don't need to be concerned with the details of the replay mechanism. It is basically something that happens behind the scenes. However, replay has two important implications for your workflow implementation.

- Do not use workflow methods to perform long-running tasks, because replay will repeat that task multiple times. Even asynchronous workflow methods typically run more than once. Instead, use activities for long running tasks; replay executes activities only once.

- Your workflow logic must be completely deterministic; every episode must take the same control flow path. For example, the control flow path should not depend on the current time. For a detailed description of replay and the determinism requirement, see Nondeterminism (p. 108).

AWS Flow Framework Basic Concepts: Task Lists and Task Execution

Amazon SWF manages workflow and activity tasks by posting them to named lists. Amazon SWF maintains at least two task lists, one for workflow workers and one for activity workers. However, you can specify as many task lists as needed, with different workers assigned to each list. You typically specify a worker's task list in the worker host application when you create the worker object. The following excerpt from the HelloWorldWorkflow host application creates a new activity worker and assigns it to the "HelloWorldList" activities task list.

```
public class GreeterWorker  {
 public static void main(String[] args) throws Exception {
        ...
  String domain = " helloWorldExamples";
  String taskListToPoll = "HelloWorldList";

  ActivityWorker aw = new ActivityWorker(service, domain, taskListToPoll);
  aw.addActivitiesImplementation(new GreeterActivitiesImpl());
  aw.start();
        ...
 }
}
```

By default, Amazon SWF will schedule the worker's tasks on the *HelloWorldList* list and the worker will poll that list for tasks. You can assign any name you prefer to a task list. You can even use the same name for both workflow and activity lists; internally, Amazon SWF puts workflow and activity task list names in different namespaces, so the two lists will be distinct.

If you don't specify a task list, the AWS Flow Framework specifies a default list when the worker registers the type with Amazon SWF. For more details, see Workflow and Activity Type Registration (p. 44).

It is sometime useful to have certain tasks performed by a specific worker or a group of workers. For example, an image processing workflow might use one activity to download an image and another activity to process the image. It is more efficient to perform both tasks on the same system, and avoid the overhead of transferring large files over the network. To support such scenarios, you can explicitly specify a task list when you call an activity client method by using an overload that includes a *schedulingOptions* parameter. You specify the task list by passing the method an appropriately configured ActivitySchedulingOptions object.

For example, suppose that the HelloWorldWorkflow application's *say* activity is hosted by a different activity worker than *getName* and `getGreeting`. The following example shows how to ensure that *say* uses the same task list as `getName` and *getGreeting*, even if they were originally assigned to different lists.

```

public class GreeterWorkflowImpl implements GreeterWorkflow {
 private GreeterActivitiesClient operations1 = new GreeterActivitiesClientIm
pl1(); //getGreeting and getName
 private GreeterActivitiesClient operations2 = new GreeterActivitiesClientIm
```

```
pl2(); //say
 @Override
 public void greet() {
  Promise<String> name = operations1.getName();
  Promise<String> greeting = operations1.getGreeting(name);
  runSay(greeting);
 }
 @Asynchronous
 private void runSay(Promise<String> greeting){
  String taskList = operations1.getSchedulingOptions().getTaskList();
  ActivitySchedulingOptions schedulingOptions = new ActivitySchedulingOptions();

  schedulingOptions.setTaskList(taskList);
  operations2.say(greeting, schedulingOptions);
 }
}
```

The asynchronous `runSay` method gets the `getGreeting` task list from its client object, and creates and configures an `ActivitySchedulingOptions` object that ensures that `say` polls the same task list as `getGreeting`.

Note

When you pass a `schedulingOptions` to an activity client method, it overrides the original task list only for that activity execution. If you call the activities client method again without specifying a task list, Amazon SWF assigns the task to the original list, and the activity worker will poll that list.

AWS Flow Framework Basic Concepts: Scalable Applications

Amazon SWF has two key features that make it easy to scale a workflow application to handle the current load:

- A complete workflow execution history, which allows you to implement a stateless application.
- Task scheduling that is loosely coupled to task execution, which makes it easy to scale your application to meet current demands.

Amazon SWF schedules tasks by posting them to dynamically allocated task lists, not by communicating directly with workflow and activity workers. Instead, the workers use HTTP requests to poll their respective lists for tasks. This approach loosely couples task scheduling to task execution and allows workers to run on any suitable system, including Amazon EC2 instances, corporate data centers, client computers, and so on. Since the HTTP requests originate with the workers, there is no need for externally visible ports, which enables workers to even run behind a firewall.

The long-polling mechanism that workers use to poll for tasks ensures that workers don't get overloaded. Even if there is a spike in scheduled tasks, workers pull tasks at their own pace. However, because workers are stateless, you can dynamically scale an application to meet increased load by starting additional worker instances. Even if they are running on different systems, each instance polls the same task list and the first available worker instance executes each task, regardless of where the worker is located or when it started. When the load declines, you can reduce the number of workers accordingly.

AWS Flow Framework Basic Concepts: Data Exchange Between Activities and Workflows

When you call an asynchronous activity client method, it immediately returns a *Promise* (also known as a *Future*) object, which represents the activity method's return value. Initially, the Promise is in an unready state and the return value is undefined. After the activity method completes its task and returns, the framework marshals the return value across the network to the workflow worker, which assigns a value to the Promise and puts the object in a ready state.

Even if an activity method has no return value, you can still use the Promise for managing workflow execution. If you pass a returned Promise to an activity client method or an asynchronous workflow method, it defers execution until object is ready.

If you pass one or more Promises to an activity client method, the framework queues the task but defers scheduling it until all the objects are ready. It then extracts the data from each Promise and marshals it across the internet to the activity worker, which passes it to the activity method as a standard type.

> **Note**
> If you need to transfer large amounts of data between workflow and activity workers, the preferred approach is to store the data in a convenient location and just pass the retrieval information. For example, you can store the data in an Amazon S3 bucket and pass the associated URL.

The Promise<T> Type

The `Promise<T>` type is similar in some ways to the Java `Future<T>` type. Both types represent values returned by asynchronous methods and are initially undefined. You access an object's value by calling its `get` method. Beyond that, the two types behave quite differently.

- `Future<T>` is a synchronization construct that allows an application to wait on an asynchronous method's completion. If you call `get` and the object is not ready, it blocks until the object is ready.
- With `Promise<T>`, synchronization is handled by the framework. If you call `get` and the object is not ready, `get` throws an exception.

The primary purpose of `Promise<T>` is to manage data flow from one activity to another. It ensures that an activity doesn't execute until the input data is valid. In many cases, workflow workers don't need to access `Promise<T>` objects directly; they simply pass the objects from one activity to another and let the framework and the activity workers handle the details. To access a `Promise<T>` object's value in a workflow worker, you must be certain that the object is ready before calling its `get` method.

- The preferred approach is to pass the `Promise<T>` object to an asynchronous workflow method and process the values there. An asynchronous method defers execution until all of its input `Promise<T>` objects are ready, which guarantees that you can safely access their values.
- `Promise<T>` exposes an `isReady` method that returns `true` if the object is ready. Using `isReady` to poll a `Promise<T>` object is not recommended, but `isReady` is useful in certain circumstances. For an example, see AWS Flow Framework Recipes.

The AWS Flow Framework for Java also includes a `Settable<T>` type, which is derived from `Promise<T>` and has similar behavior. The difference is that the framework usually sets the value of a `Promise<T>` object and the workflow worker is responsible for setting the value of a `Settable<T>` For an example, see AWS Flow Framework Recipes

There are some circumstance where a workflow worker needs to create a `Promise<T>` object and set its value. For example, an asynchronous method that returns a `Promise<T>` object needs to create a return value.

- To create an object that represents a typed value, call the static `Promise.asPromise` method, which creates a `Promise<T>` object of the appropriate type, sets its value, and puts it in the ready state.
- To create a `Promise<Void>` object, call the static `Promise.Void` method.

Note

`Promise<T>` can represent any valid type. However, if the data must be marshaled across the internet, the type must be compatible with the data converter. See the next section for details.

Data Converters and Marshaling

The AWS Flow Framework marshals data across the internet by using a data converter. By default, the framework uses a data converter that is based on the Jackson JSON processor. However, this converter has some limitations. For example, it cannot marshal maps that do not use strings as keys. If the default converter isn't sufficient for your application, you can implement a custom data converter. For details, see DataConverters (p. 71).

AWS Flow Framework Basic Concepts: Data Exchange Between Applications and Workflow Executions

A workflow entry point method can have one or more parameters, which allows the workflow starter to pass initial data to the workflow. It can also useful to provide additional data to the workflow during execution. For example, if a customer changes their shipping address, you could notify the order-processing workflow so that it can make appropriate changes.

Amazon SWF allows workflows to implement a *signal* method, which allows applications such as the workflow starter to pass data to the workflow at any time. A signal method can have any convenient name and parameters. You designate it as a signal method by including it in your workflow interface definition, and applying a `@Signal` annotation to the method declaration.

The following example shows an order processing workflow interface that declares a signal method, `changeOrder`, which allows the workflow starter to change the original order after the workflow has started.

```
@Workflow
@WorkflowRegistrationOptions(defaultExecutionStartToCloseTimeoutSeconds = 300)
public interface WaitForSignalWorkflow {
    @Execute(version = "1.0")
    public void placeOrder(int amount);
    @Signal
    public void changeOrder(int amount);
}
```

The framework's annotation processor creates a workflow client method with the same name as the signal method and the workflow starter calls the client method to pass data to the workflow. For an example, see AWS Flow Framework Recipes

Amazon SWF Timeout Types

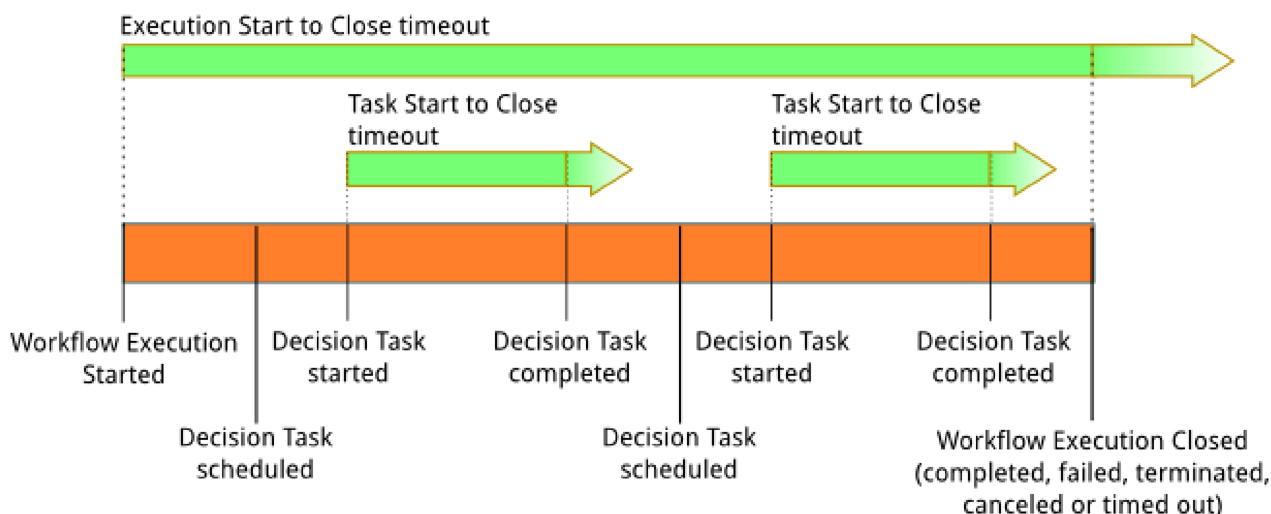
To ensure that workflow executions run correctly, Amazon SWF enables you to set different types of timeouts. Some timeouts specify how long the workflow can run in its entirety. Other timeouts specify how long activity tasks can take before being assigned to a worker and how long they can take to complete from the time they are scheduled. All timeouts in the Amazon SWF API are specified in seconds. Amazon SWF also supports the string "NONE" as a timeout value, which indicates no timeout.

For timeouts related to decision tasks and activity tasks, Amazon SWF adds an event to the workflow execution history. The attributes of the event provide information about what type of timeout occurred and which decision task or activity task was affected. Amazon SWF also schedules a decision task. When the decider receives the new decision task, it will see the timeout event in the history and take an appropriate action by calling the RespondDecisionTaskCompleted action.

A task is considered open from the time that it is scheduled until it is closed. Therefore a task is reported as open while a worker is processing it. A task is closed when a worker reports it as completed, canceled, or failed. A task may also be closed by Amazon SWF as the result of a timeout.

Timeouts in Workflow and Decision Tasks

The following diagram shows how workflow and decision timeouts are related to the lifetime of a workflow:



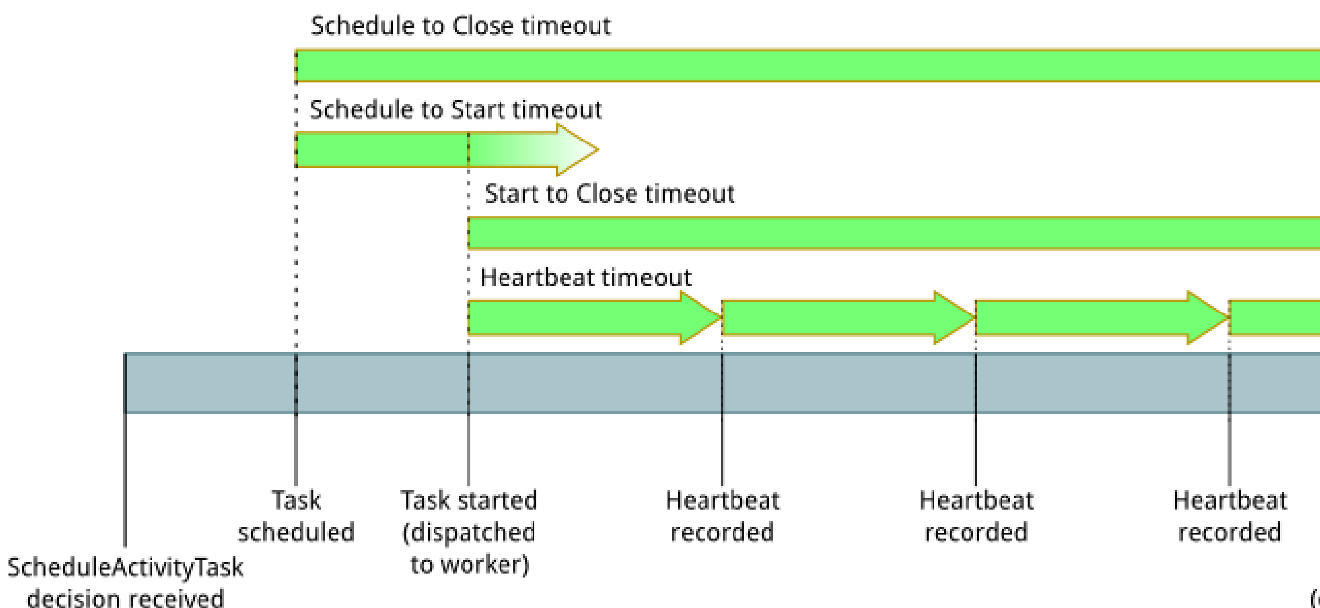
There are two timeout types that are relevant to workflow and decision tasks:

- **Workflow Start to Close (timeoutType: START_TO_CLOSE):** This timeout specifies the maximum time that a workflow execution can take to complete. It is set as a default during workflow registration, but it can be overridden with a different value when the workflow is started. If this timeout is exceeded, Amazon SWF closes the workflow execution and adds an event of type WorkflowExecutionTimedOut to the workflow execution history. In addition to the `timeoutType`, the event attributes specify the `childPolicy` that is in effect for this workflow execution. The child policy specifies how child workflow executions are handled if the parent workflow execution times out or otherwise terminates. For example, if the `childPolicy` is set to TERMINATE, then child workflow executions will be terminated. Once a workflow execution has timed out, you cannot take any action on it other than visibility calls.
- **Decision Task Start to Close (timeoutType: START_TO_CLOSE):** This timeout specifies the maximum time that the corresponding decider can take to complete a decision task. It is set during workflow type registration. If this timeout is exceeded, the task is marked as timed out in the workflow execution history, and Amazon SWF adds an event of type DecisionTaskTimedOut to the workflow history. The event attributes will include the IDs for the events that correspond to when this decision task was

scheduled (`scheduledEventId`) and when it was started (`startedEventId`). In addition to adding the event, Amazon SWF also schedules a new decision task to alert the decider that this decision task timed out. After this timeout occurs, an attempt to complete the timed-out decision task using `RespondDecisionTaskCompleted` will fail.

Timeouts in Activity Tasks

The following diagram shows how timeouts are related to the lifetime of an activity task:



There are four timeout types that are relevant to activity tasks:

- **Activity Task Start to Close (timeoutType: START_TO_CLOSE):** This timeout specifies the maximum time that an activity worker can take to process a task after the worker has received the task. Attempts to close a timed out activity task using RespondActivityTaskCanceled, RespondActivityTaskCompleted, and RespondActivityTaskFailed will fail.
- **Activity Task Heartbeat (timeoutType: HEARTBEAT):** This timeout specifies the maximum time that a task can run before providing its progress through the `RecordActivityTaskHeartbeat` action.
- **Activity Task Schedule to Start (timeoutType: SCHEDULE_TO_START):** This timeout specifies how long Amazon SWF waits before timing out the activity task if no workers are available to perform the task. Once timed out, the expired task will not be assigned to another worker.
- **Activity Task Schedule to Close (timeoutType: SCHEDULE_TO_CLOSE):** This timeout specifies how long the task can take from the time it is scheduled to the time it is complete. As a best practice, this value should not be greater than the sum of the task schedule-to-start timeout and the task start-to-close timeout.

Note
Each of the timeout types has a default value, which is generally set to NONE (infinite). The maximum time for any activity execution is limited to one year, however.

You set default values for these during activity type registration, but you can override them with new values when you schedule the activity task. When one of these timeouts occurs, Amazon SWF will add an event of type ActivityTaskTimedOut to the workflow history. The `timeoutType` value attribute of this

event will specify which of these timeouts occurred. For each of the timeouts, the value of `timeoutType` is shown in parentheses. The event attributes will also include the IDs for the events that correspond to when the activity task was scheduled (`scheduledEventId`) and when it was started (`startedEventId`). In addition to adding the event, Amazon SWF also schedules a new decision task to alert the decider that the timeout occurred.

AWS Flow Framework for Java Programming Guide

This section provides details about how to use the features of the AWS Flow Framework for Java to implement workflow applications.

Implementing Workflow Applications with the AWS Flow Framework

The typical steps involved in developing a workflow with the AWS Flow Framework are:

1. **Define activity and workflow contracts**. Analyze your application's requirements and determine the required activities, and the workflow topology. The workflow topology defines the workflows basic structure and business logic and the activities handle the required processing tasks. For example,

a media processing application needs to download a file, process it, and upload the processed file to an Amazon Simple Storage Service (S3) bucket. This can broken down into four activity tasks: download the file, process the file, upload the file to the S3 bucket, and perform clean up by deleting the local files. The workflow would have an entry point method and implement a simple linear topology that runs the activities in sequence, much like HelloWorldWorkflow Application (p. 8).

2. **Implement activity and workflow interfaces**. The workflow and activity contracts are defined by Java interfaces, which decouples the implementation from its consumers. For example, you can define a `FileProcessingWorkflow` workflow interface and provide different workflow implementations for video encoding, compression, thumbnails, and so on. Each of those workflows could have different control flows and call different activity methods; the workflow starter doesn't need to know. Interfaces also makes it easy to test your workflows by using mock implementations.
3. **Generate clients**. The AWS Flow Framework eliminates the need for you to implement the details of managing asynchronous execution, sending HTTP requests, marshaling data, and so on. Instead, the workflow starter executes a workflow instance by calling a method on the workflow client and the workflow implementation executes activities by calling methods on the activities client. The framework handles the details in the background. If you are using Eclipse and you have configured your project as described in Setting up the Development Environment (p. 2), the AWS Flow Framework annotation processor uses the interface definitions to automatically generate workflow and activities clients that expose the same set of methods as the corresponding interface.
4. **Implement activity and workflow hosts**. Your workflow and activities implementations must be embedded in host applications that poll Amazon SWF for tasks, marshal any data, and call the appropriate implementation methods. AWS Flow Framework for Java includes WorkflowWorker and ActivityWorker classes that make implementing host applications straightforward.
5. **Test your workflow**. AWS Flow Framework for Java provides JUnit integration that you can use to test your workflows inline and locally.
6. **Deploy the workers**. You can deploy your workers as appropriate—for example, you can deploy them to Amazon EC2 instances or to computers in your data center. Once deployed and started, the workers start polling Amazon SWF for tasks and handle them as required.
7. **Start executions**. An application starts a workflow instance by using the workflow client to call the workflow's entry point. You can also start workflows by using the Amazon SWF console. Regardless of how you start a workflow instance, you can use Amazon SWF console to monitor running workflow instance and examine the workflow history for running, completed, and failed instances.

The AWS SDK for Java includes a set of AWS Flow Framework for Java samples that you can browse and run by following the instructions in the readme.html file in the root folder. There are also a set of recipes —simple applications — that show how to handle a variety of specific programming issue, which are available from AWS Flow Framework Recipes.

Workflow and Activity Contracts

Java interfaces are used to declare the signatures of workflows and activities. The interface forms the contract between the implementation of the workflow (or activity) and the client of that workflow (or activity). For example, a workflow type `MyWorkflow` is defined using an interface that is annotated with the `@Workflow` annotation:

```
@Workflow
@WorkflowRegistrationOptions(defaultExecutionStartToCloseTimeoutSeconds = 60,
                          defaultTaskStartToCloseTimeoutSeconds = 10)
public interface MyWorkflow {

    @Execute(version = "1.0")
    void startMyWF(int a,
```

```
                    String b);

    @Signal
    void signal1(int a,
                 int b,
                 String c);

    @GetState
    MyWorkflowState getState();
}
```

The contract has no implementation-specific settings. This use of implementation-neutral contracts allows clients to be decoupled from the implementation and hence provides the flexibility to change the implementation details without breaking the client. Conversely, you may also change the client without necessitating changes to the workflow or activity being consumed. For example, the client may be modified to call an activity asynchronously using promises (`Promise<T>`) without requiring a change to the activity implementation. Similarly, the activity implementation may be changed so that it is completed asynchronously, for example, by a person sending an email—without requiring the clients of the activity to be changed.

In the example above, the workflow interface `MyWorkflow` contains a method, `startMyWF`, for starting a new execution. This method is annotated with the `@Execute` annotation and must have a return type of void or `Promise<>`. In a given workflow interface, at most one method can be annotated with this annotation. This method is the entry point of the workflow logic, and the framework calls this method to execute the workflow logic when a decision task is received.

The workflow interface also defines the signals that may be sent to the workflow. The signal method gets invoked when a signal with a matching name is received by the workflow execution. For example, the `MyWorkflow` interface declares a signal method, `signal1`, annotated with the `@Signal` annotation.

The `@Signal` annotation is required on signal methods. The return type of a signal method must be void. A workflow interface may have zero or more signal methods defined in it. You may declare a workflow interface without an `@Execute` method and some `@Signal` methods to generate clients that cannot start their execution but can send signals to running executions.

Methods annotated with `@Execute` and `@Signal` annotations may have any number of parameters of any type other than `Promise<T>` or its derivatives. This allows you to pass strongly typed inputs to a workflow execution at start and while it is running. The return type of the `@Execute` method must be void or `Promise<>`.

Additionally, you may also declare a method in the workflow interface to report the latest state of a workflow execution, for instance, the `getState` method in the previous example. This state is not the entire application state of the workflow. The intended use of this feature is to allow you to store up to 32 KB of data to indicate the latest status of the execution. For example, in an order processing workflow, you may store a string that indicates that the order has been received, processed, or canceled. This method is called by the framework every time a decision task is completed to get the latest state. The state is stored in Amazon Simple Workflow Service (Amazon SWF) and can be retrieved using the generated external client. This allows you to check the latest state of a workflow execution. Methods annotated with `@GetState` must not take any arguments and must not have a void return type. You can return any type, which fits your needs, from this method. In the above example, an object of `MyWorkflowState` (see definition below) is returned by the method that is used to store a string state and a numeric percent complete. The method is expected to perform read-only access of the workflow implementation object and is invoked synchronously, which disallows use of any asynchronous operations like calling methods annotated with `@Asynchronous`. At most one method in a workflow interface can be annotated with `@GetState` annotation.

```
public class MyWorkflowState {
 public String status;
 public int percentComplete;
}
```

Similarly, a set of activities are defined using an interface annotated with `@Activities` annotation. Each method in the interface corresponds to an activity—for example:

```
@Activities(version = "1.0")
@ActivityRegistrationOptions(
     defaultTaskScheduleToStartTimeoutSeconds = 300,
     defaultTaskStartToCloseTimeoutSeconds = 3600)
public interface MyActivities {

    // Overrides values from annotation found on the interface
    @ActivityRegistrationOptions(description = "This is a sample activity",
         defaultTaskScheduleToStartTimeoutSeconds = 100,

                                                                  defaultTaskStartTo
CloseTimeoutSeconds = 60)
    int activity1();

    void activity2(int a);
}
```

The interface allows you to group together a set of related activities. You can define any number of activities within an activities interface, and you can define as many activities interfaces as you want. Similar to `@Execute` and `@Signal` methods, activity methods can take any number of arguments of any type other than `Promise<T>` or its derivatives. The return type of an activity must not be `Promise<T>` or its derivatives.

Workflow and Activity Type Registration

Amazon SWF requires activity and workflow types to be registered before they can be used. The framework automatically registers the workflows and activities in the implementations you add to the worker. The framework looks for types that implement workflows and activities and registers them with Amazon SWF. By default, the framework uses the interface definitions to infer registration options for workflow and activity types. All workflow interfaces are required to have either the `@WorkflowRegistrationOptions` annotation or the `@SkipRegistration` annotation. The workflow worker registers all workflow types it is configured with that have the `@WorkflowRegistrationOptions` annotation. Similarly, each activity method is required to be annotated with either the `@ActivityRegistrationOptions` annotation or the `@SkipRegistration` annotation or one of these annotations must be present on the `@Activities` interface. The activity worker registers all activity types that it is configured with that an `@ActivityRegistrationOptions` annotation applies to. The registration is performed automatically when you start one of the workers. Workflow and activity types that have the `@SkipRegistration` annotation are not registered. `@ActivityRegistrationOptions`, and `@SkipRegistration` annotations have override semantics and the most specific one is applied to an activity type.

Note that Amazon SWF does not allow you to re-register or modify the type after it has been registered once. The framework will try to register all types, but if the type is already registered it will not be

re-registered and no error will be reported. If you need to modify registered settings, you should register a new version of the type. You can also override registered settings when starting a new execution or calling an activity using the generated clients.

The registration requires a type name and some other registration options. The default implementation determines these as follows:

Workflow Type Name and Version

The framework determines the name of the workflow type from the workflow interface. The form of the default workflow type name is {*prefix*}{*name*}. The {*prefix*} is set to the name of the `@Workflow` interface followed by a '.' and the {*name*} is set to the name of the `@Execute` method. The default name of the workflow type in the preceding example is `MyWorkflow.startMyWF`. You can override the default name using the name parameter of the `@Execute` method. The default name of the workflow type in the example is `startMyWF`. The name must not be an empty string. Note that when you override the name using `@Execute`, the framework does not automatically prepend a prefix to it. You are free to use your own naming scheme.

The workflow version is specified using the *version* parameter of the `@Workflow` annotation. There is no default for *version* and it must be explicitly specified; *version*is a free form string, and you are free to use your own versioning scheme.

Signal Name

The name of the signal can be specified using the name parameter of the `@Signal` annotation. If not specified, it is defaulted to the name of the signal method.

Activity Type Name and Version

The framework determines the name of the activity type from the activities interface. The form of the default activity type name is {*prefix*}{*name*}. The {*prefix*} is set to the name of the `@Activities` interface followed by a '.' and the {*name*} is set to the method name. The default {*prefix*} can be overridden in the `@Activities` annotation on the activities interface. You can also specify the activity type name using the `@Activity` annotation on the activity method. Note that when you override the name using `@Activity`, the framework will not automatically prepend a prefix to it. You are free to user your own naming scheme.

The activity version is specified using the version parameter of the `@Activities` annotation. This version is used as the default for all activities defined in the interface and can be overridden on a per-activity basis using the `@Activity` annotation.

Default Task List

The default task list can be configured using the `@WorkflowRegistrationOptions` and `@ActivityRegistrationOptions` annotations and setting the `defaultTaskList` parameter. By default, it is set to `USE_WORKER_TASK_LIST`. This is a special value that instructs the framework to use the task list that is configured on the worker object that is used to register the activity or workflow type. You can also choose to not register a default task list by setting the default task list to `NO_DEFAULT_TASK_LIST` using these annotations. This can be used in cases where you want to require that the task list be specified at run time. If no default task list has been registered, then you must specify the task list when starting the workflow or calling the activity method using the `StartWorkflowOptions` and `ActivitySchedulingOptions` parameters on the respective method overload of the generated client.

Other Registration Options

All workflow and activity type registration options that are allowed by the Amazon SWF API can be specified through the framework.

For a complete list of workflow type registration options, see the sections on `@Workflow` (p. 113), `@Execute` (p. 114), `@WorkflowRegistrationOptions` (p. 114), and `@Signal` (p. 115) annotations.

For a complete list of activity type registration options, see the sections on `@Activity` (p. 115), `@Activities` (p. 115), and `@ActivityRegistrationOptions` (p. 116) annotations.

If you want to have complete control over type registration, see Worker Extensibility (p. 65).

Activity and Workflow Clients

Workflow and activity clients are generated by the framework based on the `@Workflow` and `@Activities` interfaces. Separate client interfaces are generated that contain methods and settings that make sense only on the client. If you are developing using Eclipse, this is done by the Amazon SWF Eclipse plug-in every time you save the file containing the appropriate interface. The generated code is placed in the generated sources directory in your project in the same package as the interface.

> **Note**
> Note that the default directory name used by Eclipse is .apt_generated. Eclipse does not show directories whose names start with a '.' in Package Explorer. Use a different directory name if you want to view the generated files in Project Explorer. In Eclipse, right-click the package in Package Explorer, and then click **Properties** > **Java Compiler** > **Annotation processing**, and modify the **Generate source directory** setting.

Workflow Clients

The generated artifacts for the workflow contain three client-side interfaces and the classes that implement them. The generated clients include:

- A client intended to be consumed from within a workflow implementation and provides asynchronous methods to start workflow executions and send signals
- An *external* client that can be used to start executions and send signals and retrieve workflow state from outside the scope of a workflow implementation
- A *self* client that can be used to create continuous workflows

For example, the generated client interfaces for the example `MyWorkflow` interface are:

```
//Client for use from within a workflow
public interface MyWorkflowClient extends WorkflowClient
{
    Promise<Void> startMyWF(int a,
                            String b);
    Promise<Void> startMyWF(int a,
                            String b,
                            Promise<?>... waitFor);
    Promise<Void> startMyWF(int a,
                            String b,
                            StartWorkflowOptions optionsOverride,
```

```
                            Promise<?>... waitFor);
    Promise<Void> startMyWF(Promise<Integer> a,
                            Promise<String> b);
    Promise<Void> startMyWF(Promise<Integer> a,
                            Promise<String> b,
                            Promise<?>... waitFor);
    Promise<Void> startMyWF(Promise<Integer> a,
                            Promise<String> b,
                            StartWorkflowOptions optionsOverride,
                            Promise<?>... waitFor);

    void signal1(int a,
                 int b,
                 String c);
}

//External client for use outside workflows
public interface MyWorkflowClientExternal extends WorkflowClientExternal
{
    void startMyWF(int a,
                   String b);
    void startMyWF(int a,
                   String b,
                   StartWorkflowOptions optionsOverride);

    void signal1(int a,
                 int b,
                 String c);

    MyWorkflowState getState();
}

//self client for creating continuous workflows
public interface MyWorkflowSelfClient extends WorkflowSelfClient
{
    void startMyWF(int a,
                   String b);
    void startMyWF(int a,
                   String b,
                   Promise<?>... waitFor);
    void startMyWF(int a,
                   String b,
                   StartWorkflowOptions optionsOverride,
                   Promise<?>... waitFor);
    void startMyWF(Promise<Integer> a,
                   Promise<String> b);
    void startMyWF(Promise<Integer> a,
                   Promise<String> b,
                   Promise<?>... waitFor);
    void startMyWF(Promise<Integer> a,
                   Promise<String> b,
                   StartWorkflowOptions optionsOverride,
                   Promise<?>... waitFor);
}
```

The interfaces have overloaded methods corresponding to each method in the `@Workflow` interface that you declared.

The external client mirrors the methods on the `@Workflow` interface with one additional overload of the `@Execute` method that takes `StartWorkflowOptions`. You can use this overload to pass additional options when starting a new workflow execution. These options allow you to override the default task list, timeout settings, and associate tags with the workflow execution.

On the other hand, the asynchronous client has methods that allow asynchronous invocation of the `@Execute` method. The following method overloads are generated in the client interface for the `@Execute` method in the workflow interface:

1. An overload that takes the original arguments as is. The return type of this overload will be `Promise<Void>` if the original method returned void; otherwise, it will be the `Promise<>` as declared on the original method. For example:

   Original method:

   ```
   void startMyWF(int a, String b);
   ```

   Generated method:

   ```
   Promise<Void> startMyWF(int a, String b);
   ```

   This overload should be used when all the arguments of the workflow are available and don't need to be waited for.
2. An overload that takes the original arguments as is and additional variable arguments of type `Promise<?>`. The return type of this overload will be `Promise<Void>` if the original method returned void; otherwise, it will be the `Promise<>` as declared on the original method. For example:

   Original method:

   ```
   void startMyWF(int a, String b);
   ```

   Generated method:

   ```
   Promise<void> startMyWF(int a, String b, Promise<?>...waitFor);
   ```

   This overload should be used when all the arguments of the workflow are available and don't need to be waited for, but you want to wait for some other promises to become ready. The variable argument can be used to pass such `Promise<?>` objects that were not declared as arguments, but you want to wait for before executing the call.
3. An overload that takes the original arguments as is, an additional argument of type `StartWorkflowOptions` and additional variable arguments of type `Promise<?>`. The return type of this overload will be `Promise<Void>` if the original method returned void; otherwise, it will be the `Promise<>` as declared on the original method. For example:

   Original method:

   ```
   void startMyWF(int a, String b);
   ```

   Generated method:

   ```
   Promise<void> startMyWF(int a,
                           String b,
   ```

```
                                StartWorkflowOptions optionOverrides,
                                Promise<?>...waitFor);
```

This overload should be used when all the arguments of the workflow are available and don't need to be waited for, when you want to override default settings used to start the workflow execution, or when you want to wait for some other promises to become ready. The variable argument can be used to pass such `Promise<?>` objects that were not declared as arguments, but you want to wait for before executing the call.

4. An overload with each argument in the original method replaced with a `Promise<>` wrapper. The return type of this overload will be `Promise<Void>` if the original method returned void; otherwise, it will be the `Promise<>` as declared on the original method. For example:

   Original method:

   ```
   void startMyWF(int a, String b);
   ```

   Generated method:

   ```
   Promise<Void> startMyWF(Promise< Integer > a,
                                Promise<String> b);
   ```

   This overload should be used when the arguments to be passed to the workflow execution are to be evaluated asynchronously. A call to this method overload will not execute until all arguments passed to it become ready.

   If some of the arguments are already ready, then convert them to a `Promise` that is already in ready state through the `Promise.asPromise(value)` method. For example:

   ```
   Promise<Integer> a = getA();
   String b = getB();
   startMyWF(a, Promise.asPromise(b));
   ```

5. An overload with each argument in the original method is replaced with a `Promise<>` wrapper. The overload also has additional variable arguments of type `Promise<?>`. The return type of this overload will be `Promise<Void>` if the original method returned void; otherwise, it will be the `Promise<>` as declared on the original method. For example:

   Original method:

   ```
   void startMyWF(int a, String b);
   ```

   Generated method:

   ```
   Promise<void> startMyWF(Promise< Integer > a,
                                Promise<String> b,
                                Promise<?>...waitFor);
   ```

   This overload should be used when the arguments to be passed to the workflow execution are to be evaluated asynchronously and you want to wait for some other promises to become ready as well. A call to this method overload will not execute until all arguments passed to it become ready.

6. An overload with each argument in the original method replaced with a `Promise<?>` wrapper. The overload also has an additional argument of type `StartWorkflowOptions` and variable arguments of type `Promise<?>`. The return type of this overload will be `Promise<Void>` if the original method returned void; otherwise, it will be the `Promise<>` as declared on the original method. For example:

   Original method:

   ```
   void startMyWF(int a, String b);
   ```

   Generated method:

   ```
   Promise<void> startMyWF(Promise< Integer > a,
                           Promise<String> b,
                           StartWorkflowOptions optionOverrides,
                           Promise<?>...waitFor);
   ```

   Use this overload when the arguments to be passed to the workflow execution will be evaluated asynchronously and you want to override default settings used to start the workflow execution. A call to this method overload will not execute until all arguments passed to it become ready.

A method is also generated corresponding to each signal in the workflow interface—for example:

Original method:

```
void signal1(int a, int b, String c);
```

Generated method:

```
void signal1(int a, int b, String c);
```

The asynchronous client does not contain a method corresponding to the method annotated with `@GetState` in the original interface. Since retrieval of state requires a web service call, it is not suitable for use within a workflow. Hence, it is provided only through the external client.

The self client is intended to be used from within a workflow to start a new execution on completion of the current execution. The methods on this client are similar to the ones on the asynchronous client, but return void. This client does not have methods corresponding to methods annotated with `@Signal` and `@GetState`. For more details, see the Continuous Workflows (p. 70).

The generated clients derive from base interfaces: `WorkflowClient` and `WorkflowClientExternal`, respectively, which provide methods that you can use to cancel or terminate the workflow execution. For more details about these interfaces, see the AWS SDK for Java documentation.

The generated clients allow you to interact with workflow executions in a strongly typed fashion. Once created, an instance of a generated client is tied to a specific workflow execution and can be used only for that execution. In addition, the framework also provides dynamic clients that are not specific to a workflow type or execution. The generated clients rely on this client under the covers. You may also directly use these clients. See the section on Dynamic Clients (p. 55).

The framework also generates factories for creating the strongly typed clients. The generated client factories for the example `MyWorkflow` interface are:

```

//Factory for clients to be used from within a workflow
```

```
public interface MyWorkflowClientFactory
         extends WorkflowClientFactory<MyWorkflowClient> {

}

//Factory for clients to be used outside the scope of a workflow
public interface MyWorkflowClientExternalFactory {
    GenericWorkflowClientExternal getGenericClient();
    void setGenericClient(GenericWorkflowClientExternal genericClient);
    DataConverter getDataConverter();
    void setDataConverter(DataConverter dataConverter);
    StartWorkflowOptions getStartWorkflowOptions();
    void setStartWorkflowOptions(StartWorkflowOptions startWorkflowOptions);
    MyWorkflowClientExternal getClient();
    MyWorkflowClientExternal getClient(String workflowId);
    MyWorkflowClientExternal getClient(WorkflowExecution workflowExecution);
    MyWorkflowClientExternal getClient(WorkflowExecution workflowExecution,
                                 GenericWorkflowClientExternal genericClient,
                                 DataConverter dataConverter,
                                 StartWorkflowOptions options);
}
```

The `WorkflowClientFactory` base interface is:

```
public interface WorkflowClientFactory<T> {
    GenericWorkflowClient getGenericClient();
    void setGenericClient(GenericWorkflowClient genericClient);
    DataConverter getDataConverter();
    void setDataConverter(DataConverter dataConverter);
    StartWorkflowOptions getStartWorkflowOptions();
    void setStartWorkflowOptions(StartWorkflowOptions startWorkflowOptions);
    T getClient();
    T getClient(String workflowId);
    T getClient(WorkflowExecution execution);
    T getClient(WorkflowExecution execution,
                StartWorkflowOptions options);
    T getClient(WorkflowExecution execution,
                StartWorkflowOptions options,
                DataConverter dataConverter);
}
```

You should use these factories to create instances of the client. The factory allows you to configure the generic client (the generic client should be used for providing custom client implementation) and the `DataConverter` used by the client to marshal data, as well as the options used to start the *workflow execution*. For more details, see the DataConverters (p. 71) and Child Workflow Executions (p. 69) sections. The `StartWorkflowOptions` contains settings that you can use to override the defaults—for example, timeouts—specified at registration time. For more details about the `StartWorkflowOptions` class, see the AWS SDK for Java documentation.

The external client can be used to start workflow executions from outside of the scope of a workflow while the asynchronous client can be used to start a workflow execution from code within a workflow. In order to start an execution, you simply use the generated client to call the method that corresponds to the method annotated with `@Execute` in the workflow interface.

The framework also generates implementation classes for the client interfaces. These clients create and send requests to Amazon SWF to perform the appropriate action. The client version of the `@Execute` method either starts a new workflow execution or creates a child workflow execution using Amazon SWF APIs. Similarly, the client version of the `@Signal` method uses Amazon SWF APIs to send a signal.

Note: The external workflow client must be configured with the Amazon SWF client and domain. You can either use the client factory constructor that takes these as parameters or pass in a generic client implementation that is already configured with the Amazon SWF client and domain.

Note: The framework walks the type hierarchy of the workflow interface and also generates client interfaces for parent workflow interfaces and derives from them.

Activity Clients

Similar to the workflow client, a client is generated for each interface annotated with `@Activities`. The generated artifacts include a client side interface and a client class. The generated interface for the example `@Activities` interface above (`MyActivities`) is as follows:

```
public interface MyActivitiesClient extends ActivitiesClient
{
  Promise<Integer> activity1();
  Promise<Integer> activity1(Promise<?>... waitFor);
  Promise<Integer> activity1(ActivitySchedulingOptions optionsOverride,
                             Promise<?>... waitFor);
  Promise<Void> activity2(int a);
  Promise<Void> activity2(int a,
                          Promise<?>... waitFor);
  Promise<Void> activity2(int a,
                          ActivitySchedulingOptions optionsOverride,
                          Promise<?>... waitFor);
  Promise<Void> activity2(Promise<Integer> a);
  Promise<Void> activity2(Promise<Integer> a,
                          Promise<?>... waitFor);
  Promise<Void> activity2(Promise<Integer> a,
                          ActivitySchedulingOptions optionsOverride,
                          Promise<?>... waitFor);
}
```

The interface contains a set of overloaded methods corresponding to each activity method in the `@Activities` interface. These overloads are provided for convenience and allow calling activities asynchronously. For each activity method in the `@Activities` interface, the following method overloads are generated in the client interface:

1. An overload that takes the original arguments as is. The return type of this overload is `Promise<T>`, where *`T`* is the return type of the original method. For example:

   Original method:

   ```
   void activity2(int foo);
   ```

   Generated method:

   ```
   Promise<Void> activity2(int foo);
   ```

This overload should be used when all the arguments of the workflow are available and don't need to be waited for.

2. An overload that takes the original arguments as is, an argument of type `ActivitySchedulingOptions` and additional variable arguments of type `Promise<?>`. The return type of this overload is `Promise<T>`, where *T* is the return type of the original method. For example:

   Original method:

   ```
   void activity2(int foo);
   ```

   Generated method:

   ```
   Promise<Void> activity2(java.lang.Integer foo,
                           ActivitySchedulingOptions optionsOverride,
                           Promise<?>... waitFor);
   ```

   This overload should be used when all the arguments of the workflow are available and don't need to be waited for, when you want to override the default settings, or when you want to wait for additional `Promise`s to become ready. The variable arguments can be used to pass such additional `Promise<?>` objects that were not declared as arguments, but you want to wait for before executing the call.

3. An overload with each argument in the original method replaced with a `Promise<>` wrapper. The return type of this overload is `Promise<T>`, where *T* is the return type of the original method. For example:

   Original method:

   ```
   void activity2(int foo);
   ```

   Generated method:

   ```
   Promise<Void> activity2(Promise<Integer> foo);
   ```

   This overload should be used when the arguments to be passed to the activity will be evaluated asynchronously. A call to this method overload will not execute until all arguments passed to it become ready.

4. An overload with each argument in the original method replaced with a `Promise<>` wrapper. The overload also has an additional argument of type `ActivitySchedulingOptions` and variable arguments of type `Promise<?>`. The return type of this overload is `Promise<T>`, where *T* is the return type of the original method. For example:

   Original method:

   ```
   void activity2(int foo);
   ```

   Generated method:

   ```
   Promise<Void> activity2(Promise<Integer> foo,
                           ActivitySchedulingOptions optionsOverride,
                           Promise<?>...waitFor);
   ```

   This overload should be used when the arguments to be passed to the activity will be evaluated asynchronously, when you want to override the default settings registered with the type, or when you

want to wait for additional `Promise`s to become ready. A call to this method overload will not execute until all arguments passed to it become ready. The generated client class implements this interface. The implementation of each interface method creates and sends a request to Amazon SWF to schedule an activity task of the appropriate type using Amazon SWF APIs.

5. An overload that takes the original arguments as is and additional variable arguments of type `Promise<?>`. The return type of this overload is `Promise<T>`, where *T* is the return type of the original method. For example:

   Original method:

   ```
   void activity2(int foo);
   ```

   Generated method:

   ```
   Promise< Void > activity2(int foo,
                             Promise<?>...waitFor);
   ```

   This overload should be used when all the activity's arguments are available and don't need to be waited for, but you want to wait for other `Promise` objects to become ready.

6. An overload with each argument in the original method replaced with a `Promise` wrapper and additional variable arguments of type `Promise<?>`. The return type of this overload is `Promise<T>`, where *T* is the return type of the original method. For example:

   Original method:

   ```
   void activity2(int foo);
   ```

   Generated method:

   ```
   Promise<Void> activity2(java.lang.Integer foo,
                           Promise<?>... waitFor);
   ```

   This overload should be used when all the arguments of the activity will be waited for asynchronously and you also want to wait for some other `Promise`s to become ready. A call to this method overload will execute asynchronously when all `Promise` objects passed become ready.

The generated activity client also has a protected method corresponding to each activity method, named `{`*activity method name*`}Impl()`, that all activity overloads call into. You can override this method to create mock client implementations. This method takes as arguments: all the arguments to the original method in `Promise<>` wrappers, `ActivitySchedulingOptions`, and variable arguments of type `Promise<?>`. For example:

Original method:

```
void activity2(int foo);
```

Generated method:

```
Promise<Void> activity2Impl(Promise<Integer> foo,
                            ActivitySchedulingOptions optionsOverride,
                            Promise<?>...waitFor);
```

Scheduling Options

The generated activity client allows you to pass in `ActivitySchedulingOptions` as an argument. The `ActivitySchedulingOptions` structure contains settings that determine the configuration of the activity task that the framework schedules in Amazon SWF. These settings override the defaults that are specified as registration options. To specify scheduling options dynamically, create an `ActivitySchedulingOptions` object, configure it as desired, and pass it to the activity method. In the following example, we have specified the task list that should be used for the activity task. This will override the default registered task list for this invocation of the activity.

```
public class OrderProcessingWorkflowImpl implements OrderProcessingWorkflow {

    OrderProcessingActivitiesClient activitiesClient
            = new OrderProcessingActivitiesClientImpl();

    // Workflow entry point
    @Override
    public void processOrder(Order order) {
       Promise<Void> paymentProcessed = activitiesClient.processPayment(order);

        ActivitySchedulingOptions schedulingOptions
             = new ActivitySchedulingOptions();
        if (order.getLocation() == "Japan") {
            schedulingOptions.setTaskList("TasklistAsia");
        } else {
            schedulingOptions.setTaskList("TasklistNorthAmerica");
        }

        activitiesClient.shipOrder(order,
                                   schedulingOptions,
                                   paymentProcessed);
    }
}
```

Dynamic Clients

In addition to the generated clients, the framework also provides general purpose clients—`DynamicWorkflowClient` and `DynamicActivityClient`—that you can use to dynamically start workflow executions, send signals, schedule activities, etc. For instance, you may want to schedule an activity whose type is not known at design time. You can use the `DynamicActivityClient` for scheduling such an activity task. Similarly, you can dynamically schedule a child workflow execution by using the `DynamicWorkflowClient`. In the following example, the workflow looks up the activity from a database and uses the dynamic activity client to schedule it:

```
//Workflow entrypoint
@Override
public void start() {
 MyActivitiesClient client = new MyActivitiesClientImpl();
  Promise<ActivityType> activityType
      = client.lookUpActivityFromDB();
  Promise<String> input = client.getInput(activityType);
```

```
  scheduleDynamicActivity(activityType,
                          input);
}
@Asynchronous
void scheduleDynamicActivity(Promise<ActivityType> type,
                             Promise<String> input){
  Promise<?>[] args = new Promise<?>[1];
 args[0] = input;
 DynamicActivitiesClient activityClient
     = new DynamicActivitiesClientImpl();
 activityClient.scheduleActivity(type.get(),
                                 args,
                                 null,
                                 Void.class);
}
```

For more details, see the AWS SDK for Java documentation.

Signaling and Canceling Workflow Executions

The generated workflow client has methods corresponding to each signal that can be sent to the workflow. You can use them from within a workflow to send signals to other workflow executions. This provides a typed mechanism for sending signals. However, sometimes you may need to dynamically determine the signal name—for example, when the signal name is received in a message. You can use the dynamic workflow client to dynamically send signals to any workflow execution. Similarly, you can use the client to request cancellation of another workflow execution.

In the following example, the workflow looks up the execution to send a signal to from a database and sends the signal dynamically using the dynamic workflow client.

```
//Workflow entrypoint
public void start() {
  MyActivitiesClient client = new MyActivitiesClientImpl();
  Promise<WorkflowExecution> execution
      = client.lookUpExecutionInDB();
  Promise<String> signalName = client.getSignalToSend();
  Promise<String> input = client.getInput(signalName);
  sendDynamicSignal(execution,
                    signalName,
                    input);
}
@Asynchronous
void sendDynamicSignal(Promise<WorkflowExecution> execution,
                       Promise<String> signalName,
                       Promise<String> input){
  DynamicWorkflowClient workflowClient
      = new DynamicWorkflowClientImpl(execution.get());
  Object[] args = new Promise<?>[1];
  args[0] = input.get();
  workflowClient.signalWorkflowExecution(signalName.get(),
                                         args);
}
```

Workflow Implementation

In order to implement a workflow, you write a class that implements the desired `@Workflow` interface. For instance, the example workflow interface (`MyWorkflow`) can be implemented like so:

```
public class MyWFImpl implements MyWorkflow
{
  MyActivitiesClient client = new MyActivitiesClientImpl();
  @Override
  public void startMyWF(int a, String b){
    Promise<Integer> result = client.activity1();
    client.activity2(result);
  }
  @Override
  public void signal1(int a, int b, String c){
    //Process signal
     client.activity2(a + b);
  }
}
```

The `@Execute` method in this class is the entry point of the workflow logic. Since the framework uses replay to reconstruct the object state when a decision task is to be processed, a new object is created for each decision task.

The use of `Promise<T>` as a parameter is disallowed in the `@Execute` method within a `@Workflow` interface. This is done because making an asynchronous call is purely a decision of the caller. The workflow implementation itself doesn't depend on whether the invocation was synchronous or asynchronous. Therefore, the generated client interface has overloads that take `Promise<T>` parameters so that these methods can be called asynchronously.

The return type of an `@Execute` method can only be void or `Promise<T>`. Note that a return type of the corresponding external client is void and not `Promise<>`. Since the external client is not intended to be used from the asynchronous code, the external client does not return `Promise` objects. For getting results of workflow executions stated externally, you can design the workflow to update state in an external data store through an activity. Amazon SWF's visibility APIs can also be used to retrieve the result of a workflow for diagnostic purposes. It is not recommended that you use the visibility APIs to retrieve results of workflow executions as a general practice since these API calls may get throttled by Amazon SWF. The visibility APIs require you to identify the workflow execution using a `WorkflowExecution` structure. You can get this structure from the generated workflow client by calling the `getWorkflowExecution` method. This method will return the `WorkflowExecution` structure corresponding to the workflow execution that the client is bound to. See the Amazon Simple Workflow Service API Reference for more details about the visibility APIs.

When calling activities from your workflow implementation, you should use the generated activities client. Similarly, to send signals, use the generated workflow clients.

Decision Context

The framework provides an ambient context anytime workflow code is executed by the framework. This context provides context-specific functionality that you may access in your workflow implementation, such as creating a timer. See the section on Execution Context (p. 66) for more information.

Exposing Execution State

Amazon SWF allows you to add custom state in the workflow history. The latest state reported by the workflow execution is returned to you through visibility calls to the Amazon SWF service and in the Amazon SWF console. For example, in an order processing workflow, you may report the order status at different stages like ‘order received’, ‘order shipped’, and so on. In the AWS Flow Framework for Java, this is accomplished through a method on your workflow interface that is annotated with the `@GetState` annotation. When the decider is done processing a decision task, it calls this method to get the latest state from the workflow implementation. Besides visibility calls, the state can also be retrieved using the generated external client (which uses the visibility API calls internally).

The following example demonstrates how to set the execution context.

```
@Workflow
@WorkflowRegistrationOptions(defaultExecutionStartToCloseTimeoutSeconds = 60,
               defaultTaskStartToCloseTimeoutSeconds = 10)
public interface PeriodicWorkflow {

    @Execute(version = "1.0")
    void periodicWorkflow();

    @GetState
    String getState();
}

@Activities(version = "1.0")
@ActivityRegistrationOptions(defaultTaskScheduleToStartTimeoutSeconds = 300,
                             defaultTaskStartToCloseTimeoutSeconds = 3600)
public interface PeriodicActivity {
    void activity1();

}

public class PeriodicWorkflowImpl implements PeriodicWorkflow {

    private DecisionContextProvider contextProvider
             = new DecisionContextProviderImpl();

    private WorkflowClock clock
             = contextProvider.getDecisionContext().getWorkflowClock();

    private PeriodicActivityClient activityClient
             = new PeriodicActivityClientImpl();

    private String state;

    @Override
    public void periodicWorkflow() {
        state = "Just Started";
        callPeriodicActivity(0);
    }

    @Asynchronous
    private void callPeriodicActivity(int count,
                                      Promise<?>... waitFor)
    {
```

```
        if(count == 100) {
            state = "Finished Processing";
            return;
        }

        // call activity
        activityClient.activity1();

        // Repeat the activity after 1 hour.
        Promise<Void> timer = clock.createTimer(3600);
        state = "Waiting for timer to fire. Count = "+count;
        callPeriodicActivity(count+1, timer);
    }

    @Override
    public String getState() {
        return state;
    }
}

public class PeriodicActivityImpl implements PeriodicActivity
{
@Override
    public static void activity1()
 {
  ...
    }
}
```

The generated external client can be used to retrieve the latest state of the workflow execution at any time.

```
PeriodicWorkflowClientExternal client
        = new PeriodicWorkflowClientExternalFactoryImpl().getClient();
System.out.println(client.getState());
```

In the above example, the execution state is reported at various stages. When the workflow instance starts, `periodicWorkflow` reports the initial state as 'Just Started'. Each call to `callPeriodicActivity` then updates the workflow state. Once `activity1` has been called 100 times, the method returns and the workflow instance completes.

Workflow Locals

Sometimes, you may have a need for the use of static variables in your workflow implementation. For example, you may want to store a counter that is to be accessed from various places (possibly different classes) in the implementation of the workflow. However, you cannot rely on static variables in your workflows because static variables are shared across threads, which is problematic because a worker may process different decision tasks on different threads at the same time. Alternatively, you may store such state in a field on the workflow implementation, but then you will need to pass the implementation object around. To address this need, the framework provides a `WorkflowExecutionLocal<>` class. Any state that needs to have static variable like semantics should be kept as an instance local using `WorkflowExecutionLocal<>`. You can declare and use a static variable of this type. For example, in the following snippet, a `WorkflowExecutionLocal<String>` is used to store a user name.

```
public class MyWFImpl implements MyWF {
  public static WorkflowExecutionLocal<String> username
      = new WorkflowExecutionLocal<String>();

  @Override
  public void start(String username){
    this.username.set(username);
    Processor p = new Processor();
    p.updateLastLogin();
    p.greetUser();
 }

  public static WorkflowExecutionLocal<String> getUsername() {
    return username;
  }

  public static void setUsername(WorkflowExecutionLocal<String> username) {
    MyWFImpl.username = username;
  }
}

public class Processor {
  void updateLastLogin(){
    UserActivitiesClient c = new UserActivitiesClientImpl();
    c.refreshLastLogin(MyWFImpl.getUsername().get());
  }
 void greetUser(){
    GreetingActivitiesClient c = new GreetingActivitiesClientImpl();
    c.greetUser(MyWFImpl.getUsername().get());
  }
}
```

Activity Implementation

Activities are implemented by providing an implementation of the `@Activities` interface. The AWS Flow Framework for Java uses the activity implementation instances configured on the worker to process activity tasks at run time. The worker automatically looks up the activity implementation of the appropriate type.

You can use properties and fields to pass resources to activity instances, such as database connections. Since the activity implementation object may be accessed from multiple threads, shared resources must be thread safe.

Note that the activity implementation does not take parameters of type `Promise<>` or return objects of that type. This is because the implementation of the activity should not depend on how it was invoked (synchronously or asynchronously).

The activities interface shown before can be implemented like this:

```
public class MyActivitiesImpl implements MyActivities {

 @Override
 @ManualActivityCompletion
```

```
 public int activity1(){
  //implementation
 }

 @Override
 public void activity2(int foo){
   //implementation
 }
}
```

A thread local context is available to the activity implementation that can be used to retrieve the task object, data converter object being used, etc. The current context can be accessed through `ActivityExecutionContextProvider.getActivityExecutionContext()`. For more details, see the AWS SDK for Java documentation for `ActivityExecutionContext` and the section Execution Context (p. 66).

Manually Completing Activities

The `@ManualActivityCompletion` annotation in the example above is an optional annotation. It is allowed only on methods that implement an activity and is used to configure the activity to not automatically complete when the activity method returns. This could be useful when you want to complete the activity asynchronously—for example, manually after a human action has been completed.

By default, the framework considers the activity completed when your activity method returns. This means that the activity worker reports activity task completion to Amazon SWF and provides it with the results (if any). However, there are use cases where you don't want the activity task to be marked completed when the activity method returns. This is especially useful when you are modeling human tasks. For example, the activity method may send an email to a person who must complete some work before the activity task is completed. In such cases, you can annotate the activity method with `@ManualActivityCompletion` annotation to tell the activity worker that it should not complete the activity automatically. In order to complete the activity manually, you can either use the `ManualActivityCompletionClient` provided in the framework or use the `RespondActivityTaskCompleted` method on the Amazon SWF Java client provided in the Amazon SWF SDK. For more details, see the AWS SDK for Java documentation.

In order to complete the activity task, you need to provide a task token. The task token is used by Amazon SWF to uniquely identify tasks. You can access this token from the `ActivityExecutionContext` in your activity implementation. You must pass this token to the party that is responsible for completing the task. This token can be retrieved from the `ActivityExecutionContext` by calling `ActivityExecutionContextProvider.getActivityExecutionContext().getTaskToken()`.

The `getName` activity of the Hello World example can be implemented to send an email asking someone to provide a greeting message:

```
@ManualActivityCompletion
@Override
public String getName() throws InterruptedException {
    ActivityExecutionContext executionContext
         = contextProvider.getActivityExecutionContext();
    String taskToken = executionContext.getTaskToken();
    sendEmail("abc@xyz.com",
         "Please provide a name for the greeting message and close task with
token: " + taskToken);
    return "This will not be returned to the caller";
}
```

The following code snippet can be used to provide the greeting and close the task by using the `ManualActivityCompletionClient`. Alternatively, you can also fail the task:

```
public class CompleteActivityTask {

    public void completeGetNameActivity(String taskToken) {

        AmazonSimpleWorkflow swfClient
           = new AmazonSimpleWorkflowClient(…); // use AWS access keys
        ManualActivityCompletionClientFactory manualCompletionClientFactory
           = new ManualActivityCompletionClientFactoryImpl(swfClient);
        ManualActivityCompletionClient manualCompletionClient
           = manualCompletionClientFactory.getClient(taskToken);
        String result = "Hello World!";
        manualCompletionClient.complete(result);
    }

    public void failGetNameActivity(String taskToken, Throwable failure) {
        AmazonSimpleWorkflow swfClient
           = new AmazonSimpleWorkflowClient(…); // use AWS access keys
        ManualActivityCompletionClientFactory manualCompletionClientFactory
           = new ManualActivityCompletionClientFactoryImpl(swfClient);
        ManualActivityCompletionClient manualCompletionClient
           = manualCompletionClientFactory.getClient(taskToken);
        manualCompletionClient.fail(failure);
    }

}
```

Running Programs Written with the AWS Flow Framework for Java

Topics

- WorkflowWorker (p. 63)
- ActivityWorker (p. 64)
- Worker Threading Model (p. 64)
- Worker Extensibility (p. 65)

The framework provides *worker classes* to initialize the AWS Flow Framework for Java runtime and communicate with Amazon SWF. In order to implement a workflow or an activity worker, you must create and start an instance of a worker class. These worker classes are responsible for managing ongoing asynchronous operations, invoking asynchronous methods that become unblocked, and communicating with Amazon SWF. They can be configured with workflow and activity implementations, the number of threads, the task list to poll, and so on.

The framework comes with two worker classes, one for activities and one for workflows. In order to run the workflow logic, you use the `WorkflowWorker` class. Similarly for activities the `ActivityWorker` class is used. These classes automatically poll Amazon SWF for activity tasks and invoke the appropriate methods in your implementation.

The following example shows how to instantiate a `WorkflowWorker` and start polling for tasks:

```
AmazonSimpleWorkflow swfClient = new AmazonSimpleWorkflowClient(awsCredentials);
WorkflowWorker worker = new WorkflowWorker(swfClient, "domain1", "tasklist1");
// Add workflow implementation types
worker.addWorkflowImplementationType(MyWorkflowImpl.class);

// Start worker
worker.start();
```

The basic steps to create an instance of the `ActivityWorker` and starting polling for tasks are as follows:

```
AmazonSimpleWorkflow swfClient
      = new AmazonSimpleWorkflowClient(awsCredentials);
ActivityWorker worker = new ActivityWorker(swfClient,
                                            "domain1",
                                            "tasklist1");
worker.addActivitiesImplementation(new MyActivitiesImpl());

// Start worker
worker.start();
```

When you want to shut down an activity or decider, your application should shut down the instances of the worker classes being used as well as the Amazon SWF Java client instance. This will ensure that all resources used by the worker classes are properly released.

```
worker.shutdown();
worker.awaitTermination(1, TimeUnit.MINUTES);
```

In order to start an execution, simply create an instance of the generated external client and call the `@Execute` method.

```
MyWorkflowClientExternalFactory factory = new MyWorkflowClientExternalFactory
Impl();
MyWorkflowClientExternal client = factory.getClient();
client.start();
```

WorkflowWorker

As the name suggests, this worker class is intended for use by the workflow implementation. It is configured with a task list and the workflow implementation type. The worker class runs a loop to poll for decision tasks in the specified task list. When a decision task is received, it creates an instance of the workflow implementation and calls the `@Execute` method to process the task.

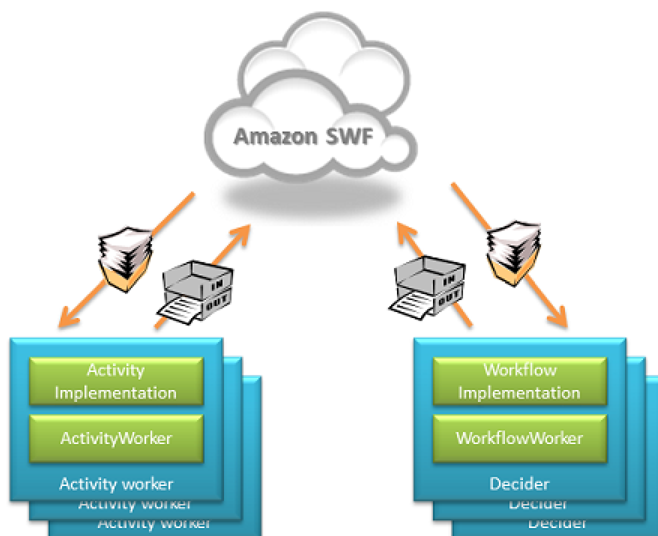
ActivityWorker

For implementing activity workers, you can use the `ActivityWorker` class to conveniently poll a task list for activity tasks. You configure the activity worker with activity implementation objects. This worker class runs a loop to poll for activity tasks in the specified task list. When an activity task is received, it looks up the appropriate implementation that you provided and calls the activity method to process the task. Unlike the `WorkflowWorker`, which calls the factory to create a new instance for every decision task, the `ActivityWorker` simply uses the object you provided.

The `ActivityWorker` class uses the AWS Flow Framework for Java annotations to determine the registration and execution options.

Worker Threading Model

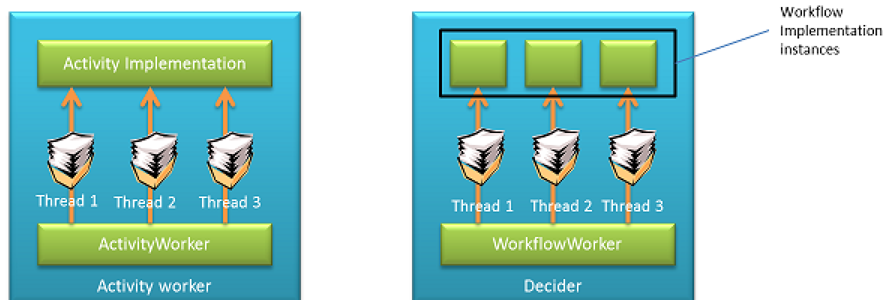
In the AWS Flow Framework for Java, the embodiment of an activity or decider is an instance of the worker class. Your application is responsible for configuring and instantiating the worker object on each machine and process that should act as a worker. The worker object then automatically receives tasks from Amazon SWF, dispatches them to your activity or workflow implementation and reports results to Amazon SWF. It is possible for a single workflow instance to span many workers. When Amazon SWF has one or more pending activity tasks, it assigns a task to the first available worker, then the next one, and so on. This makes it possible for tasks belonging to the same workflow instance to be processed on different workers concurrently.



Moreover, each worker can be configured to process tasks on multiple threads. This means that the activity tasks of a workflow instance can run concurrently even if there is only one worker.

Decision tasks behave similarly with the exception that Amazon SWF guarantees that for a given workflow execution only one decision can be executed at a time. A single workflow execution will typically require multiple decision tasks; hence, it may end up executing on multiple processes and threads as well. The decider is configured with the type of the workflow implementation. When a decision task is received by the decider, it creates an instance (object) of the workflow implementation. The framework provides an extensible factory pattern for creating these instances. The default workflow factory creates a new object every time. You can provide custom factories to override this behavior.

Contrary to deciders, which are configured with workflow implementation types, activity workers are configured with instances (objects) of the activity implementations. When an activity task is received by the activity worker, it is dispatched to the appropriate activity implementation object.



The workflow worker maintains a single pool of threads and executes the workflow on the same thread that was used to poll Amazon SWF for the task. Since activities are long running (at least when compared to the workflow logic), the activity worker class maintains two separate pools of threads; one for polling Amazon SWF for activity tasks and the other for processing tasks by executing the activity implementation. This allows you to configure the number of threads to poll for tasks separate from the number of threads to execute them. For example, you can have a small number of threads to poll and a large number of threads to execute the tasks. The activity worker class polls Amazon SWF for a task only when it has a free poll thread as well as a free thread to process the task.

This threading and instancing behavior implies that:

1. Activity implementations must be stateless. You should not use instance variables to store application state in activity objects. You may, however, use fields to store resources such as database connections.
2. Activity implementations must be thread safe. Since the same instance may be used to process tasks from different threads at the same time, access to shared resources from the activity code must be synchronized.
3. Workflow implementation can be stateful, and instance variables may be used to store state. Even though a new instance of the workflow implementation is created to process each decision task, the framework will ensure that state is properly recreated. However, the workflow implementation must be deterministic. See the section Under the Hood (p. 104) for more details.
4. Workflow implementations don't need to be thread safe when using the default factory. The default implementation ensures that only one thread uses an instance of the workflow implementation at a time.

Worker Extensibility

The AWS Flow Framework for Java also contains a couple of low-level worker classes that give you fine-grained control as well as extensibility. Using them, you can completely customize workflow and activity type registration and set factories for creating implementation objects. These workers are `GenericWorkflowWorker` and `GenericActivityWorker`.

The `GenericWorkflowWorker` can be configured with a factory for creating workflow definition factories. The workflow definition factory is responsible for creating instances of the workflow implementation and for providing configuration settings such as registration options. Under normal circumstances, you should use the `WorkflowWorker` class directly. It will automatically create and configure implementation of the factories provided in the framework, `POJOWorkflowDefinitionFactoryFactory` and `POJOWorkflowDefinitionFactory`. The factory requires that the workflow implementation class must have a no argument constructor. This constructor is used to create instances of the workflow object at run time. The factory looks at the annotations you used on the workflow interface and implementation to create appropriate registration and execution options.

You may provide your own implementation of the factories by implementing `WorkflowDefinitionFactory`, `WorkflowDefinitionFactoryFactory`, and `WorkflowDefinition`. The `WorkflowDefinition` class is used by the worker class to dispatch decision tasks and signals. By implementing these base classes, you can completely customize the factory and the dispatch of requests to the workflow implementation. For example, you can use these extensibility points to provide a custom programming model for writing workflows, for instance, based on your own annotations or generating it from WSDL instead of the code first approach used by the framework. In order to use your custom factories, you will have to use the `GenericWorkflowWorker` class. For more details about these classes, see the AWS SDK for Java documentation.

Similarly, `GenericActivityWorker` allows you to provide a custom activity implementation factory. By implementing the `ActivityImplementationFactory` and `ActivityImplementation` classes you can completely control activity instantiation as well as customize registration and execution options. For more details of these classes, see the AWS SDK for Java documentation.

Execution Context

Topics

- Decision Context (p. 66)
- Activity Execution Context (p. 68)

The framework provides an ambient context to workflow and activity implementations. This context is specific to the task being processed and provides some utilities that you can use in your implementation. A context object is created every time a new task is processed by the worker.

Decision Context

When a decision task is executed, the framework provides the context to workflow implementation through the `DecisionContext` class. `DecisionContext` provides context-sensitive information like workflow execution run Id and clock and timer functionality.

Accessing DecisionContext in Workflow Implementation

You can access the `DecisionContext` in your workflow implementation using the `DecisionContextProviderImpl` class. Alternatively, you can inject the context in a field or property of your workflow implementation using Spring as shown in the Testability and Dependency Injection section.

```
DecisionContextProvider contextProvider
    = new DecisionContextProviderImpl();
DecisionContext context = contextProvider.getDecisionContext();
```

Creating a Clock and Timer

The `DecisionContext` contains a property of type `WorkflowClock` that provides timer and clock functionality. Since the workflow logic needs to be deterministic, you should not directly use the system clock in your workflow implementation. The `currentTimeMills` method on the `WorkflowClock` returns the time of the start event of the decision being processed. This ensures that you get the same time value during replay, hence, making your workflow logic deterministic.

`WorkflowClock` also has a `createTimer` method which returns a `Promise` object that becomes ready after the specified interval. You can use this value as a parameter to other asynchronous methods to

delay their execution by the specified period of time. This way you can effectively *schedule* an asynchronous method or activity for execution at a later time.

The example in the following listing demonstrates how to periodically call an activity.

```
@Workflow
@WorkflowRegistrationOptions(defaultExecutionStartToCloseTimeoutSeconds = 60,
               defaultTaskStartToCloseTimeoutSeconds = 10)
public interface PeriodicWorkflow {

    @Execute(version = "1.0")
    void periodicWorkflow();
}

@Activities(version = "1.0")
@ActivityRegistrationOptions(defaultTaskScheduleToStartTimeoutSeconds = 300,
                             defaultTaskStartToCloseTimeoutSeconds = 3600)
public interface PeriodicActivity {
    void activity1();
}

public class PeriodicWorkflowImpl implements PeriodicWorkflow {

    private DecisionContextProvider contextProvider
         = new DecisionContextProviderImpl();

    private WorkflowClock clock
         = contextProvider.getDecisionContext().getWorkflowClock();

    @Override
    public void periodicWorkflow() {
        callPeriodicActivity(0);
    }

    @Asynchronous
    private void callPeriodicActivity(int count,
                                      Promise<?>... waitFor) {
        if (count == 100) {
            return;
        }
        PeriodicActivityClient client = new PeriodicActivityClientImpl();
        // call activity
        Promise<Void> activityCompletion = client.activity1();

        Promise<Void> timer = clock.createTimer(3600);

        // Repeat the activity either after 1 hour or after previous activity
run
        // if it takes longer than 1 hour
        callPeriodicActivity(count + 1, timer, activityCompletion);
    }
}

public class PeriodicActivityImpl implements PeriodicActivity
{
@Override
   public void activity1() {
```

```
    ...
        }
}
```

In the above listing, the `callPeriodicActivity` asynchronous method calls `activity1` and then creates a timer using the current `AsyncDecisionContext`. It passes the returned `Promise` as an argument to a recursive call to itself. This recursive call waits until the timer fires (1 hour in this example) before executing.

Activity Execution Context

Just as the `DecisionContext` provides context information when a decision task is being processed, `ActivityExecutionContext` provides similar context information when an activity task is being processed. This context is available to your activity code through `ActivityExecutionContextProviderImpl` class.

```
ActivityExecutionContextProvider provider
    = new ActivityExecutionContextProviderImpl();
ActivityExecutionContext aec = provider.getActivityExecutionContext();
```

Using `ActivityExecutionContext`, you can perform the following:

Heartbeat a Long Running Activity

If the activity is long running, it must periodically report its progress to Amazon SWF to let it know that the task is still making progress. In the absence of such a heartbeat, the task may timeout if a task heartbeat timeout was set at activity type registration or while scheduling the activity. In order to send a heartbeat, you can use the `recordActivityHeartbeat` method on `ActivityExecutionContext`. Heartbeat also provides a mechanism for canceling ongoing activities. See the Error Handling (p. 84) section for more details and an example.

Get Details of the Activity Task

If you want, you can get all the details of the activity task that were passed by Amazon SWF when the executor got the task. This includes information regarding the inputs to the task, task type, task token, etc. If you want to implement an activity that is manually completed—for example, by a human action—then you must use the `ActivityExecutionContext` to retrieve the task token and pass it to the process that will eventually complete the activity task. See the section on Manually Completing Activities (p. 61) for more details.

Get the Amazon SWF Client Object that is Being Used by the Executor

The Amazon SWF client object being used by the executor can be retrieved by calling `getService` method on `ActivityExecutionContext`. This is useful if you want to make a direct call to the Amazon SWF service.

Child Workflow Executions

In the examples so far, we have started workflow execution directly from an application. However, a workflow execution may be started from within a workflow by calling the workflow entry point method on the generated client. When a workflow execution is started from the context of another workflow execution, it is called a child workflow execution. This allows you to refactor complex workflows into smaller units and potentially share them across different workflows. For example, you can create a payment processing workflow and call it from an order processing workflow.

Semantically, the child workflow execution behaves the same as a standalone workflow except for the following differences:

1. When the parent workflow terminates due to an explicit action by the user—for example, by calling the `TerminateWorkflowExecution` Amazon SWF API, or it is terminated due to a timeout—then the fate of the child workflow execution will be determined by a child policy. You can set this child policy to terminate, cancel, or abandon (keep running) child workflow executions.
2. The output of the child workflow (return value of the entry point method) can be used by the parent workflow execution just like the `Promise<T>` returned by an asynchronous method. This is different from standalone executions where the application must get the output by using Amazon SWF APIs.

In the following example, the `OrderProcessor` workflow creates a `PaymentProcessor` child workflow:

```
@Workflow
@WorkflowRegistrationOptions(defaultExecutionStartToCloseTimeoutSeconds = 60,
              defaultTaskStartToCloseTimeoutSeconds = 10)
public interface OrderProcessor {

    @Execute(version = "1.0")
    void processOrder(Order order);
}

public class OrderProcessorImpl implements OrderProcessor {
    PaymentProcessorClientFactory factory
         = new PaymentProcessorClientFactoryImpl();

    @Override
    public void processOrder(Order order) {
        float amount = order.getAmount();
        CardInfo cardInfo = order.getCardInfo();

        PaymentProcessorClient childWorkflowClient = factory.getClient();
        childWorkflowClient.processPayment(amount, cardInfo);
    }

}

@Workflow
@WorkflowRegistrationOptions(defaultExecutionStartToCloseTimeoutSeconds = 60,
                 defaultTaskStartToCloseTimeoutSeconds = 10)
public interface PaymentProcessor {

    @Execute(version = "1.0")
    void processPayment(float amount, CardInfo cardInfo);

}
```

```
public class PaymentProcessorImpl implements PaymentProcessor {
   PaymentActivitiesClient activitiesClient = new PaymentActivitiesClientImpl();

    @Override
    public void processPayment(float amount, CardInfo cardInfo) {
       Promise<PaymentType> payType = activitiesClient.getPaymentType(cardInfo);

        switch(payType.get()) {
        case Visa:
            activitiesClient.processVisa(amount, cardInfo);
            break;
        case Amex:
            activitiesClient.processAmex(amount, cardInfo);
            break;
     default:
      throw new UnSupportedPaymentTypeException();
        }
    }

}

@Activities(version = "1.0")
@ActivityRegistrationOptions(defaultTaskScheduleToStartTimeoutSeconds = 3600,
                             defaultTaskStartToCloseTimeoutSeconds = 3600)
public interface PaymentActivities {

    PaymentType getPaymentType(CardInfo cardInfo);

    void processVisa(float amount, CardInfo cardInfo);

    void processAmex(float amount, CardInfo cardInfo);

}
```

Continuous Workflows

In some use cases, you may need a workflow that executes forever or runs for a long duration, for example, a workflow that monitors the health of a server fleet. Since Amazon SWF keeps the entire history of a workflow execution, the history will keep growing over time. The framework retrieves this history from Amazon SWF when it performs a replay and this will become expensive if the history size is too large. In such long running or continuous workflows, you should periodically close the current execution and start a new one to continue processing. This is a logical continuation of the workflow execution. The generated self client can be used for this purpose. In your workflow implementation, simply call the `@Execute` method on the self client. Once the current execution completes, the framework will start a new execution using the same workflow Id.

You can also continue the execution by calling the `continueAsNewOnCompletion` method on the `GenericWorkflowClient` that you can retrieve from the current `DecisionContext`. For example, the following workflow implementation sets a timer to fire after a day and calls its own entry point to start a new execution.

```
public class ContinueAsNewWorkflowImpl implements ContinueAsNewWorkflow {
```

```
    private DecisionContextProvider contextProvider
         = new DecisionContextProviderImpl();

    private ContinueAsNewWorkflowSelfClient selfClient
         = new ContinueAsNewWorkflowSelfClientImpl();

    private WorkflowClock clock
         = contextProvider.getDecisionContext().getWorkflowClock();

    @Override
    public void startWorkflow() {
        Promise<Void> timer = clock.createTimer(86400);
        continueAsNew(timer);
    }

    @Asynchronous
    void continueAsNew(Promise<Void> timer) {
        selfClient.startWorkflow();
    }
}
```

When a workflow recursively calls itself, the framework will close the current workflow when all pending tasks have completed and start a new workflow execution. Note that as long as there are pending tasks, the current workflow execution will not close. The new execution will not automatically inherit any history or data from the original execution; if you want to carry over some state to the new execution, then you must pass it explicitly as input.

DataConverters

When your workflow implementation calls a remote activity, the inputs passed to it and the result of executing the activity must be serialized so they can be sent over the wire. The framework uses the DataConverter class for this purpose. This is an abstract class that you can implement to provide your own serializer. A default Jackson serializer–based implementation, `JsonDataConverter`, is provided in the framework. For more details, see the AWS SDK for Java documentation. Refer to the Jackson JSON Processor documentation for details about how Jackson performs serialization as well as Jackson annotations that can be used to influence it. The wire format used is considered part of the contract. Hence, you can specify a `DataConverter` on your activities and workflow interfaces by setting the `DataConverter` property of the `@Activities` and `@Workflow` annotations.

The framework will create objects of the `DataConverter` type you specified on `@Activities` annotation to serialize the inputs of to the activity and to deserialize its result. Similarly, objects of the `DataConverter` type you specify on `@Workflow` annotation will be used to serialize parameters you pass to the workflow, and in the case of child workflow, to deserialize the result. In addition to inputs, the framework also passes additional data to Amazon SWF—for example, exception details—the workflow serializer will be used for serializing this data as well.

You can also provide an instance of the `DataConverter` if you don't want the framework to automatically create it. The generated clients have constructor overloads that take a `DataConverter`. You can also provide it to the worker classes by having your activity or workflow implement the `DataConverterFactory` interface.

If you don't specify a `DataConverter` type and don't pass a `DataConverter` object, the `JsonDataConverter` will be used by default.

Passing Data to Asynchronous Methods

Topics

- Passing Collections and Maps to Asynchronous Methods (p. 72)
- Settable<T> (p. 73)
- @NoWait (p. 74)
- Promise<Void> (p. 74)
- AndPromise and OrPromise (p. 74)

The use of `Promise<T>` has been explained in previous sections. Some advanced use cases of `Promise<T>` are discussed here.

Passing Collections and Maps to Asynchronous Methods

The framework supports passing arrays, collections, and maps as `Promise` types to asynchronous methods. For example, an asynchronous method may take `Promise<ArrayList<String>>` as an argument as shown in the following listing.

```
@Asynchronous
public void printList(Promise<List<String>> list) {
    for (String s: list.get()) {
        activityClient.printActivity(s);
    }
}
```

Semantically, this behaves as any other `Promise` typed parameter and the asynchronous method will wait until the collection becomes available before executing. If the members of a collection are `Promise` objects, then you can make the framework wait for all members to become ready as shown in the following snippet. This will make the asynchronous method wait on each member of the collection to become available.

```
@Asynchronous
public void printList(@Wait List<Promise<String>> list) {
  for (Promise<String> s: list) {
    activityClient.printActivity(s);
  }
}
```

Note that the `@Wait` annotation must be used on the parameter to indicate that it contains `Promise` objects.

Note also that the activity `printActivity` takes a `String` argument but the matching method in the generated client takes a Promise<String>. We are calling the method on the client and not invoking the activity method directly.

Settable<T>

`Settable<T>` is a derived type of `Promise<T>` that provides a set method that allows you to manually set the value of a `Promise`. For example, the following workflow waits for a signal to be received by waiting on a `Settable<>`, which is set in the signal method:

```
public class MyWorkflowImpl implements MyWorkflow{
 final Settable<String> result = new Settable<String>();

 //@Execute method
 @Override
 public Promise<String> start() {
  return done(result);
 }

 //Signal
 @Override
 public void manualProcessCompletedSignal(String data) {
  result.set(data);
 }

 @Asynchronous
 public Promise<String> done(Settable<String> result){
   return result;
 }
}
```

A `Settable<>` can also be chained to another promise at a time. You can use `AndPromise` and `OrPromise` to group promises. You can unchain a chained `Settable` by calling the `unchain()` method on it. When chained, the `Settable<>` automatically becomes ready when the promise that it is chained to becomes ready. Chaining is especially useful when you want to use a promise returned from within the scope of a `doTry()` in other parts of your program. Since `TryCatchFinally` is used as a nested class, you cannot declare a `Promise<>` in the parent's scope and set it in `doTry()`. This is because Java requires variables to be declared in parent scope and used in nested classes to be marked final. For example:

```
@Asynchronous
public Promise<String> chain(final Promise<String> input) {
    final Settable<String> result = new Settable<String>();

    new TryFinally() {

        @Override
        protected void doTry() throws Throwable {
            Promise<String> resultToChain = activity1(input);
            activity2(resultToChain);

            // Chain the promise to Settable
            result.chain(resultToChain);
        }

        @Override
        protected void doFinally() throws Throwable {
            if (result.isReady()) { // Was a result returned before the excep
```

```
tion?
                    // Do cleanup here
               }
          }
     };

     return result;
}
```

A `Settable` can be chained to one promise at a time. You can unchain a chained `Settable` by calling the `unchain()` method on it.

@NoWait

When you pass a `Promise` to an asynchronous method, by default, the framework will wait for the `Promise`(s) to become ready before executing the method (except for collection types). You may override this behavior by using the `@NoWait` annotation on parameters in the declaration of the asynchronous method. This is useful if you are passing in `Settable<T>`, which will be set by the asynchronous method itself.

Promise<Void>

Dependencies in asynchronous methods are implemented by passing the `Promise` returned by one method as an argument to another. However, there may be cases where you want to return void from a method, but still want other asynchronous methods to execute after its completion. In such cases, you can use `Promise<Void>` as the return type of the method. The `Promise` class provides a static `Void` method that you can use to create a `Promise<Void>` object. This `Promise` will become ready when the asynchronous method finishes execution. You can pass this `Promise` to another asynchronous method just like any other `Promise` object. If you are using `Settable<Void>`, then call the set method on it with null to make it ready.

AndPromise and OrPromise

`AndPromise` and `OrPromise` allow you to group multiple `Promise<>` objects into a single logical promise. An `AndPromise` becomes ready when all promises used to construct it become ready. An `OrPromise` becomes ready when any promise in the collection of promises used to construct it becomes ready. You can call `getValues()` on `AndPromise` and `OrPromise` to retrieve the list of values of the constituent promises.

Testability and Dependency Injection

Topics

- Spring Integration (p. 75)
- JUnit Integration (p. 80)

The framework is designed to be Inversion of Control (IoC) friendly. Activity and workflow implementations as well as the framework supplied workers and context objects can be configured and instantiated using containers like Spring. Out of the box, the framework provides integration with the Spring Framework. In addition, integration with JUnit has been provided for unit testing workflow and activity implementations.

Spring Integration

The com.amazonaws.services.simpleworkflow.flow.spring package contains classes that make it easy to use the Spring framework in your applications. These include a custom Scope and Spring-aware activity and workflow workers: `WorkflowScope`, `SpringWorkflowWorker` and `SpringActivityWorker`. These classes allow you to configure your workflow and activity implementations as well as the workers entirely through Spring.

WorkflowScope

`WorkflowScope` is a custom Spring Scope implementation provided by the framework. This scope allows you to create objects in the Spring container whose lifetime is scoped to that of a decision task. The beans in this scope are instantiated every time a new decision task is received by the worker. You should use this scope for workflow implementation beans and any other beans it depends on. The Spring-provided singleton and prototype scopes should not be used for workflow implementation beans because the framework requires that a new bean be created for each decision task. Failure to do so will result in unexpected behavior.

The following example shows a snippet of Spring configuration that registers the `WorkflowScope` and then uses it for configuring a workflow implementation bean and an activity client bean.

```
<!--  register &awsflow-java; WorkflowScope -->
<bean class="org.springframework.beans.factory.config.CustomScopeConfigurer">

  <property name="scopes">
   <map>
   <entry key="workflow">
    <bean class="com.amazonaws.services.simpleworkflow.flow.spring.WorkflowScope"
/>
   </entry>
   </map>
  </property>
</bean>

<!--  activities client -->
<bean id="activitiesClient" class="aws.flow.sample.MyActivitiesClientImpl"
scope="workflow">
</bean>

<!-- workflow implementation -->
<bean id="workflowImpl" class="aws.flow.sample.MyWorkflowImpl" scope="workflow">

  <property name="client" ref="activitiesClient"/>
  <aop:scoped-proxy proxy-target-class="false" />
</bean>
```

The line of configuration: `<aop:scoped-proxy proxy-target-class="false" />`, used in the configuration of the `workflowImpl` bean, is required because the `WorkflowScope` does not support proxying using CGLIB. You should use this configuration for any bean in the `WorkflowScope` that is wired to another bean in a different scope. In this case, the `workflowImpl` bean needs to be wired to a workflow worker bean in singleton scope (see complete example below).

You can learn more about using custom scopes in the Spring Framework documentation.

Spring-Aware Workers

When using Spring, you should use the Spring-aware worker classes provided by the framework: `SpringWorkflowWorker` and `SpringActivityWorker`. These workers can be injected in your application using Spring as shown in the next example. The Spring-aware workers implement Spring's `SmartLifecycle` interface and, by default, automatically start polling for tasks when the Spring context is initialized. You can turn off this functionality by setting the `disableAutoStartup` property of the worker to `true`.

The following example shows how to configure a decider. This example uses `MyActivities` and `MyWorkflow` interfaces (not shown here) and corresponding implementations, `MyActivitiesImpl` and `MyWorkflowImpl`. The generated client interfaces and implementations are `MyWorkflowClient`/`MyWorkflowClientImpl` and `MyActivitiesClient`/`MyActivitiesClientImpl` (also not shown here).

The activities client is injected in the workflow implementation using Spring's auto wire feature:

```
public class MyWorkflowImpl implements MyWorkflow {
 @Autowired
 public MyActivitiesClient client;

 @Override
 public void start() {
  client.activity1();
 }
}
```

The Spring configuration for the decider is as follows:

```
<?xml version="1.0" encoding="UTF-8"?>
<beans xmlns="http://www.springframework.org/schema/beans"
 xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xmlns:aop="http://www.springframework.org/schema/aop"
 xmlns:context="http://www.springframework.org/schema/context"
 xsi:schemaLocation="http://www.springframework.org/schema/beans ht
tp://www.springframework.org/schema/beans/spring-beans.xsd
 http://www.springframework.org/schema/aop http://www.springframe
work.org/schema/aop/spring-aop-2.5.xsd
 http://www.springframework.org/schema/context
    http://www.springframework.org/schema/context/spring-context-3.0.xsd">

 <!--  register custom workflow scope -->
 <bean class="org.springframework.beans.factory.config.CustomScopeConfigurer">

  <property name="scopes">
   <map>
   <entry key="workflow">
    <bean class="com.amazonaws.services.simpleworkflow.flow.spring.WorkflowScope"
 />
   </entry>
   </map>
  </property>
```

```
 </bean>
 <context:annotation-config/>

 <bean id="accesskeys" class="com.amazonaws.auth.BasicAWSCredentials">
  <constructor-arg value="{AWS.Access.ID}"/>
  <constructor-arg value="{AWS.Secret.Key}"/>
 </bean>

 <bean id="clientConfiguration" class="com.amazonaws.ClientConfiguration">
  <property name="socketTimeout" value="70000" />
 </bean>

 <!-- &SWF; client -->
 <bean id="swfClient"
  class="com.amazonaws.services.simpleworkflow.AmazonSimpleWorkflowClient">
  <constructor-arg ref="accesskeys" />
  <constructor-arg ref="clientConfiguration" />
  <property name="endpoint" value="{service.url}" />
 </bean>

 <!--  activities client -->
 <bean id="activitiesClient" class="aws.flow.sample.MyActivitiesClientImpl"
scope="workflow">
 </bean>

 <!-- workflow implementation -->
 <bean id="workflowImpl" class="aws.flow.sample.MyWorkflowImpl" scope="workflow">

  <property name="client" ref="activitiesClient"/>
  <aop:scoped-proxy proxy-target-class="false" />
 </bean>

 <!--  workflow worker -->
 <bean id="workflowWorker"
  class="com.amazonaws.services.simpleworkflow.flow.spring.SpringWorkflowWorker">

  <constructor-arg ref="swfClient" />
  <constructor-arg value="domain1" />
  <constructor-arg value="tasklist1" />
  <property name="registerDomain" value="true" />
  <property name="domainRetentionPeriodInDays" value="1" />
  <property name="workflowImplementations">
   <list>
    <ref bean="workflowImpl" />
   </list>
  </property>
 </bean>
</beans>
```

Since the `SpringWorkflowWorker` is fully configured in Spring and automatically starts polling when the Spring context is initialized, the host process for the decider is simple:

```
public class WorkflowHost {
 public static void main(String[] args){
  ApplicationContext context
```

```
      = new FileSystemXmlApplicationContext("resources/spring/WorkflowHost
Bean.xml");
  System.out.println("Workflow worker started");
 }
}
```

Similarly, the activity worker can be configured as follows:

```
<?xml version="1.0" encoding="UTF-8"?>
<beans xmlns="http://www.springframework.org/schema/beans"
 xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xmlns:aop="http://www.springframework.org/schema/aop"
 xmlns:context="http://www.springframework.org/schema/context"
 xsi:schemaLocation="http://www.springframework.org/schema/beans ht
tp://www.springframework.org/schema/beans/spring-beans.xsd
 http://www.springframework.org/schema/aop http://www.springframe
work.org/schema/aop/spring-aop-2.5.xsd
 http://www.springframework.org/schema/context
    http://www.springframework.org/schema/context/spring-context-3.0.xsd">

 <!--  register custom scope -->
 <bean class="org.springframework.beans.factory.config.CustomScopeConfigurer">

  <property name="scopes">
   <map>
    <entry key="workflow">
     <bean
      class="com.amazonaws.services.simpleworkflow.flow.spring.WorkflowScope"
/>
    </entry>
   </map>
  </property>
 </bean>

 <bean id="accesskeys" class="com.amazonaws.auth.BasicAWSCredentials">
  <constructor-arg value="{AWS.Access.ID}"/>
  <constructor-arg value="{AWS.Secret.Key}"/>
 </bean>

 <bean id="clientConfiguration" class="com.amazonaws.ClientConfiguration">
  <property name="socketTimeout" value="70000" />
 </bean>

 <!-- &SWF; client -->
 <bean id="swfClient"
  class="com.amazonaws.services.simpleworkflow.AmazonSimpleWorkflowClient">
  <constructor-arg ref="accesskeys" />
  <constructor-arg ref="clientConfiguration" />
  <property name="endpoint" value="{service.url}" />
 </bean>

 <!-- activities impl -->
 <bean name="activitiesImpl" class="asadj.spring.test.MyActivitiesImpl">
 </bean>
```

```
 <!-- activity worker -->
 <bean id="activityWorker"
  class="com.amazonaws.services.simpleworkflow.flow.spring.SpringActivityWorker">

  <constructor-arg ref="swfClient" />
  <constructor-arg value="domain1" />
  <constructor-arg value="tasklist1" />
  <property name="registerDomain" value="true" />
  <property name="domainRetentionPeriodInDays" value="1" />
  <property name="activitiesImplementations">
   <list>
    <ref bean="activitiesImpl" />
   </list>
  </property>
 </bean>
</beans>
```

The activity worker host process is similar to the decider:

```
public class ActivityHost {
 public static void main(String[] args) {
  ApplicationContext context = new FileSystemXmlApplicationContext(
  "resources/spring/ActivityHostBean.xml");
  System.out.println("Activity worker started");
 }
}
```

Injecting Decision Context

If your workflow implementation depends on the context objects, then you can easily inject them through Spring as well. The framework automatically registers context-related beans in the Spring container. For example, in the following snippet, the various context objects have been auto wired. No other Spring configuration of the context objects is required.

```
public class MyWorkflowImpl implements MyWorkflow {
 @Autowired
 public MyActivitiesClient client;
 @Autowired
 public WorkflowClock clock;
 @Autowired
 public DecisionContext dcContext;
 @Autowired
 public GenericActivityClient activityClient;
 @Autowired
 public GenericWorkflowClient workflowClient;
 @Autowired
 public WorkflowContext wfContext;
 @Override
 public void start() {
  client.activity1();
 }
```

```
}
```

If you want to configure the context objects in the workflow implementation through Spring XML configuration, then use the bean names declared in the `WorkflowScopeBeanNames` class in the com.amazonaws.services.simpleworkflow.flow.spring package. For example:

```
<!-- workflow implementation -->
<bean id="workflowImpl" class="asadj.spring.test.MyWorkflowImpl" scope="work
flow">
 <property name="client" ref="activitiesClient"/>
 <property name="clock" ref="workflowClock"/>
 <property name="activityClient" ref="genericActivityClient"/>
 <property name="dcContext" ref="decisionContext"/>
 <property name="workflowClient" ref="genericWorkflowClient"/>
 <property name="wfContext" ref="workflowContext"/>
 <aop:scoped-proxy proxy-target-class="false" />
</bean>
```

Alternatively, you may inject a `DecisionContextProvider` in the workflow implementation bean and use it to create the context. This can be useful if you want to provide custom implementations of the provider and context.

Injecting Resources in Activities

You can instantiate and configure activity implementations using an Inversion of Control (IoC) container and easily inject resources like database connections by declaring them as properties of the activity implementation class. Such resources will typically be scoped as singletons. Note that activity implementations are called by the activity worker on multiple threads. Therefore, access to shared resources must be synchronized.

JUnit Integration

The framework provides JUnit extensions as well as test implementations of the context objects, such as a test clock, that you can use to write and run unit tests with JUnit. With these extensions, you can test your workflow implementation locally inline.

Writing a Simple Unit Test

In order to write tests for your workflow, use the `WorkflowTest` class in the com.amazonaws.services.simpleworkflow.flow.junit package. This class is a framework-specific JUnit `MethodRule` implementation and runs your workflow code locally, calling activities inline as opposed to going through Amazon SWF. This gives you the flexibility to run your tests as frequently as you desire without incurring any charges.

In order to use this class, simply declare a field of type `WorkflowTest` and annotate it with the `@Rule` annotation. Before running your tests, create a new `WorkflowTest` object and add your activity and workflow implementations to it. You can then use the generated workflow client factory to create a client and start an execution of the workflow. The framework also provides a custom JUnit runner, `FlowBlockJUnit4ClassRunner`, that you must use for your workflow tests. For example:

```
@RunWith(FlowBlockJUnit4ClassRunner.class)
public class BookingWorkflowTest {

    @Rule
    public WorkflowTest workflowTest = new WorkflowTest();

    List<String> trace;

    private BookingWorkflowClientFactory workflowFactory
         = new BookingWorkflowClientFactoryImpl();

    @Before
    public void setUp() throws Exception {
        trace = new ArrayList<String>();
        // Register activity implementation to be used during test run
        BookingActivities activities = new BookingActivitiesImpl(trace);
        workflowTest.addActivitiesImplementation(activities);
        workflowTest.addWorkflowImplementationType(BookingWorkflowImpl.class);

    }

    @After
    public void tearDown() throws Exception {
        trace = null;
    }

    @Test
    public void testReserveBoth() {
        BookingWorkflowClient workflow = workflowFactory.getClient();
        Promise<Void> booked = workflow.makeBooking(123, 345, true, true);
        List<String> expected = new ArrayList<String>();
        expected.add("reserveCar-123");
        expected.add("reserveAirline-123");
        expected.add("sendConfirmation-345");
        AsyncAssert.assertEquals("invalid booking", expected, trace, booked);
    }
}
```

You can also specify a separate task list for each activity implementation that you add to `WorkflowTest`. For example, if you have a workflow implementation that schedules activities in host-specific task lists, then you can register the activity in the task list of each host:

```
for (int i = 0; i < 10; i++) {
    String hostname = "host" + i;
    workflowTest.addActivitiesImplementation(hostname,
                                            new ImageProcessingActivities(host
name));
}
```

Notice that the code in the `@Test` is asynchronous. Therefore, you should use the asynchronous workflow client to start an execution. In order to verify the results of your test, an `AsyncAssert` help class is also provided. This class allows you to wait for promises to become ready before verifying results. In this example, we wait for the result of the workflow execution to be ready before verifying the test output.

If you are using Spring, then the `SpringWorkflowTest` class can be used instead of the `WorkflowTest` class. `SpringWorkflowTest` provides properties that you can use to configure activity and workflow implementations easily through Spring configuration. Just like the Spring-aware workers, you should use the `WorkflowScope` to configure workflow implementation beans. This ensures that a new workflow implementation bean is created for every decision task. Make sure to configure these beans with the scoped-proxy proxy-target-class setting set to `false`. See the Spring Integration section for more details. The example Spring configuration shown in the Spring Integration section can be changed to test the workflow using `SpringWorkflowTest`:

```
<?xml version="1.0" encoding="UTF-8"?>
<beans xmlns="http://www.springframework.org/schema/beans"
  xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance" xmlns:aop="ht
tp://www.springframework.org/schema/aop"
  xmlns:context="http://www.springframework.org/schema/context"
  xsi:schemaLocation="http://www.springframework.org/schema/beans ht

          <key>
            <value>list1</value>
          </key>
          <ref bean="activitiesImplHost1" />
        </entry>
      </map>
    </property>
  </bean>
</beans>
```

Mocking Activity Implementations

You may use the real activity implementations during testing, but if you want to unit test just the workflow logic, you should mock the activities. This can do this by providing a mock implementation of the activities interface to the `WorkflowTest` class. For example:

```
@RunWith(FlowBlockJUnit4ClassRunner.class)
public class BookingWorkflowTest {

    @Rule
    public WorkflowTest workflowTest = new WorkflowTest();

    List<String> trace;

    private BookingWorkflowClientFactory workflowFactory
         = new BookingWorkflowClientFactoryImpl();

    @Before
    public void setUp() throws Exception {
        trace = new ArrayList<String>();
        // Create and register mock activity implementation to be used during
test run
        BookingActivities activities = new BookingActivities() {

            @Override
            public void sendConfirmationActivity(int customerId) {
                trace.add("sendConfirmation-" + customerId);
            }

            @Override
            public void reserveCar(int requestId) {
```

```
                trace.add("reserveCar-" + requestId);
            }

            @Override
            public void reserveAirline(int requestId) {
                trace.add("reserveAirline-" + requestId);
            }
        };
        workflowTest.addActivitiesImplementation(activities);
        workflowTest.addWorkflowImplementationType(BookingWorkflowImpl.class);

    }

    @After
    public void tearDown() throws Exception {
        trace = null;
    }

    @Test
    public void testReserveBoth() {
        BookingWorkflowClient workflow = workflowFactory.getClient();
        Promise<Void> booked = workflow.makeBooking(123, 345, true, true);
        List<String> expected = new ArrayList<String>();
        expected.add("reserveCar-123");
        expected.add("reserveAirline-123");
        expected.add("sendConfirmation-345");
        AsyncAssert.assertEquals("invalid booking", expected, trace, booked);
    }
}
```

Alternatively, you can provide a mock implementation of the activities client and inject that into your workflow implementation.

Test Context Objects

If your workflow implementation depends on the framework context objects—for example, the `DecisionContext`—you don't have to do anything special to test such workflows. When a test is run through `WorkflowTest`, it automatically injects test context objects. When your workflow implementation accesses the context objects—for example, using `DecisionContextProviderImpl`—it will get the test implementation. You can manipulate these test context objects in your test code (`@Test` method) to create interesting test cases. For example, if your workflow creates a timer, you can make the timer fire by calling the `clockAdvanceSeconds` method on the `WorkflowTest` class to move the clock forward in time. You can also accelerate the clock to make timers fire earlier than they normally would using the `ClockAccelerationCoefficient` property on `WorkflowTest`. For example, if your workflow creates a timer for one hour, you can set the `ClockAccelerationCoefficient` to 60 to make the timer fire in one minute. By default, `ClockAccelerationCoefficient` is set to 1.

For more details about the com.amazonaws.services.simpleworkflow.flow.test and com.amazonaws.services.simpleworkflow.flow.junit packages, see the AWS SDK for Java documentation.

Error Handling

Topics

- TryCatchFinally Semantics (p. 86)

- Cancellation (p. 87)
- Nested TryCatchFinally (p. 90)
- Retry Failed Activities (p. 91)

The `try/catch/finally` construct in Java makes it simple to handle errors and is used ubiquitously. It allows you to associate error handlers to a block of code. Internally, this works by stuffing additional metadata about the error handlers on the call stack. When an exception is thrown, the runtime looks at the call stack for an associated error handler and invokes it; and if no appropriate error handler is found, it propagates the exception up the call chain.

This works well for synchronous code, but handling errors in asynchronous and distributed programs poses additional challenges. Since an asynchronous call returns immediately, the caller is not on the call stack when the asynchronous code executes. This means that unhandled exceptions in the asynchronous code cannot be handled by the caller in the usual way. Typically, exceptions that originate in asynchronous code are handled by passing error state to a callback that is passed to the asynchronous method. Alternatively, if a `Future<>` is being used, it reports an error when you try to access it. This is less than ideal because the code that receives the exception (the callback or code that uses the `Future<>`) does not have the context of the original call and may not be able to handle the exception adequately. Furthermore, in a distributed asynchronous system, with components running concurrently, more than one error may occur simultaneously. These errors could be of different types and severities and need to be handled appropriately.

Cleaning up resource after an asynchronous call is also difficult. Unlike synchronous code, you cannot use try/catch/finally in the calling code to clean up resources since work initiated in the try block may still be ongoing when the finally block executes.

The framework provides a mechanism that makes error handling in distributed asynchronous code similar to, and almost as simple as, Java's try/catch/finally.

```
ImageProcessingActivitiesClient activitiesClient
     = new ImageProcessingActivitiesClientImpl();

public void createThumbnail(final String webPageUrl) {

  new TryCatchFinally() {

    @Override
    protected void doTry() throws Throwable {
      List<String> images = getImageUrls(webPageUrl);
      for (String image: images) {
        Promise<String> localImage
            = activitiesClient.downloadImage(image);
        Promise<String> thumbnailFile
            = activitiesClient.createThumbnail(localImage);
        activitiesClient.uploadImage(thumbnailFile);
      }
    }

    @Override
    protected void doCatch(Throwable e) throws Throwable {

      // Handle exception and rethrow failures
      LoggingActivitiesClient logClient = new LoggingActivitiesClientImpl();
      logClient.reportError(e);
      throw new RuntimeException("Failed to process images", e);
```

```
    }

    @Override
    protected void doFinally() throws Throwable {
      activitiesClient.cleanUp();
    }
  };
}
```

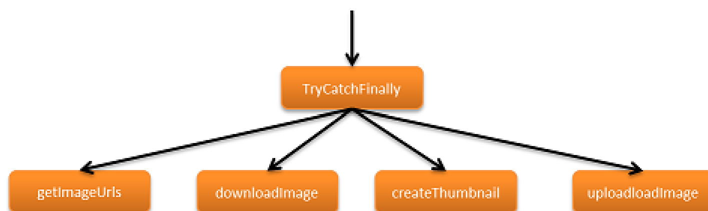
The `TryCatchFinally` class and its variants, `TryFinally` and `TryCatch`, work similar to Java's `try/catch/finally`. Using it, you can associate exception handlers to blocks of workflow code that may execute as asynchronous and remote tasks. The `doTry()` method is logically equivalent to the `try` block. The framework automatically executes the code in `doTry()`. A list of `Promise` objects can be passed to the constructor of `TryCatchFinally`. The `doTry` method will be executed when all `Promise` objects passed in to the constructor become ready. If an exception is raised by code that was asynchronously invoked from within `doTry()`, any pending work in `doTry()` is canceled and `doCatch()` is called to handle the exception. For instance, in the listing above, if `downloadImage` throws an exception, then `createThumbnail` and `uploadImage` will be canceled. Finally, `doFinally()` is called when all asynchronous work is done (completed, failed, or canceled). It can be used for resource cleanup. You can also nest these classes to suit your needs.

When an exception is reported in `doCatch()`, the framework provides a complete logical call stack that includes asynchronous and remote calls. This can be helpful when debugging, especially if you have asynchronous methods calling other asynchronous methods. For example, an exception from downloadImage will produce an exception like this:

```
RuntimeException: error downloading image
  at downloadImage(Main.java:35)
  at ---continuation---.(repeated:1)
  at errorHandlingAsync$1.doTry(Main.java:24)
  at ---continuation---.(repeated:1)
…
```

TryCatchFinally Semantics

The execution of an AWS Flow Framework for Java program can be visualized as a tree of concurrently executing branches. A call to an asynchronous method, an activity, and `TryCatchFinally` itself creates a new branch in this tree of execution. For example, the image processing workflow can be viewed as the tree shown in the following figure.



An error in one branch of execution will cause the unwinding of that branch, just as an exception causes the unwinding of the call stack in a Java program. The unwinding keeps moving up the execution branch until either the error is handled or the root of the tree is reached, in which case the workflow execution is terminated.

The framework reports errors that happen while processing tasks as exceptions. It associates the exception handlers (`doCatch()` methods) defined in `TryCatchFinally` with all tasks that are created by the code

in the corresponding `doTry()`. If a task fails—for example, due to a timeout or an unhandled exception—then the appropriate exception will be raised and the corresponding `doCatch()` will be invoked to handle it. To accomplish this, the framework works in tandem with Amazon SWF to propagate remote errors and resurrects them as exceptions in the caller's context.

Cancellation

When an exception occurs in synchronous code, the control jumps directly to the `catch` block, skipping over any remaining code in the `try` block. For example:

```
try {
    a();
    b();
    c();
}
catch (Exception e) {
    e.printStackTrace();
}
```

In this code, if `b()` throws an exception, then `c()` is never invoked. Compare that to a workflow:

```
new TryCatch() {

    @Override
    protected void doTry() throws Throwable {
        activityA();
        activityB();
        activityC();
    }

    @Override
    protected void doCatch(Throwable e) throws Throwable {
        e.printStackTrace();
    }
};
```

In this case, calls to `activityA`, `activityB`, and `activityC` all return successfully and result in the creation of three tasks that will be executed asynchronously. Let's say at a later time that the task for `activityB` results in an error. This error is recorded in the history by Amazon SWF. In order to handle this, the framework will first try to cancel all other tasks that originated within the scope of the same `doTry()`; in this case, `activityA` and `activityC`. When all such tasks complete (cancel, fail, or successfully complete), the appropriate `doCatch()` method will be invoked to handle the error.

Unlike the synchronous example, where `c()` was never executed, `activityC` was invoked and a task was scheduled for execution; hence, the framework will make an attempt to cancel it, but there is no guarantee that it will be canceled. Cancellation cannot be guaranteed because the activity may have already completed, may ignore the cancellation request, or may fail due to an error. However, the framework does provide the guarantee that `doCatch()` is called only after all tasks started from the corresponding `doTry()` have completed. It also guarantees that `doFinally()` is called only after all tasks started from the `doTry()` and `doCatch()` have completed. If, for instance, the activities in the above example depend on each other, say `activityB` depends on `activityA` and `actvityC` on `activityB`, then the cancellation of `activityC` will be immediate because it is not scheduled in Amazon SWF until `activityB` completes:

```
new TryCatch() {

    @Override
    protected void doTry() throws Throwable {
        Promise<Void> a = activityA();
        Promise<Void> b = activityB(a);
        activityC(b);
    }

    @Override
    protected void doCatch(Throwable e) throws Throwable {
        e.printStackTrace();
    }
};
```

Activity Heartbeat

The AWS Flow Framework for Java's cooperative cancellation mechanism allows in-flight activity tasks to be canceled gracefully. When cancellation is triggered, tasks that blocked or are waiting to be assigned to a worker are automatically canceled. If, however, a task is already assigned to a worker, the framework will request the activity to cancel. Your activity implementation must explicitly handle such cancellation requests. This is done by reporting heartbeat of your activity.

Reporting heartbeat allows the activity implementation to report the progress of an ongoing activity task, which is useful for monitoring, and it lets the activity check for cancellation requests. The `recordActivityHeartbeat` method will throw a `CancellationException` if a cancellation has been requested. The activity implementation can catch this exception and act on the cancellation request, or it can ignore the request by swallowing the exception. In order to honor the cancellation request, the activity should perform the desired clean up, if any, and then rethrow `CancellationException`. When this exception is thrown from an activity implementation, the framework records that the activity task has been completed in canceled state.

The following example shows an activity that downloads and processes images. It heartbeats after processing each image, and if cancellation is requested, it cleans up and rethrows the exception to acknowledge cancellation.

```
@Override
public void processImages(List<String> urls) {
    int imageCounter = 0;
    for (String url: urls) {
        imageCounter++;
        Image image = download(url);
        process(image);
        try {
            ActivityExecutionContext context
                 = contextProvider.getActivityExecutionContext();
            context.recordActivityHeartbeat(Integer.toString(imageCounter));
        } catch(CancellationException ex) {
            cleanDownloadFolder();
            throw ex;
        }
    }
```

```
}
```

Reporting activity heartbeat is not required, but it is recommended if your activity is long running or may be performing expensive operations that you wish to be canceled under error conditions. You should call `heartbeatActivityTask` periodically from the activity implementation.

If the activity times out, the `ActivityTaskTimedOutException` will be thrown and `getDetails` on the exception object will return the data passed to the last successful call to `heartbeatActivityTask` for the corresponding activity task. The workflow implementation may use this information to determine how much progress was made before the activity task was timed out.

Note: It is not a good practice to heartbeat too frequently because Amazon SWF may throttle heartbeat requests. See the Amazon Simple Workflow Service Developer Guide for limits placed by Amazon SWF.

Explicitly Canceling a Task

Besides error conditions, there are other cases where you may explicitly cancel a task. For example, an activity to process payments using a credit card may need to be canceled if the user cancels the order. The framework allows you to explicitly cancel tasks created in the scope of a `TryCatchFinally`. In the following example, the payment task is canceled if a signal is received while the payment was being processed.

```
public class OrderProcessorImpl implements OrderProcessor {
    private PaymentProcessorClientFactory factory
        = new PaymentProcessorClientFactoryImpl();
    boolean processingPayment = false;
    private TryCatchFinally paymentTask = null;

    @Override
    public void processOrder(int orderId, final float amount) {
        paymentTask = new TryCatchFinally() {

            @Override
            protected void doTry() throws Throwable {
                processingPayment = true;

                PaymentProcessorClient paymentClient = factory.getClient();
                paymentClient.processPayment(amount);
            }

            @Override
            protected void doCatch(Throwable e) throws Throwable {
                if (e instanceof CancellationException) {
                    paymentClient.log("Payment canceled.");
                } else {
                    throw e;
                }
            }

            @Override
            protected void doFinally() throws Throwable {
                processingPayment = false;
            }
        };
```

```
    }

    @Override
    public void cancelPayment() {
        if (processingPayment) {
            paymentTask.cancel(null);
        }
    }
}
```

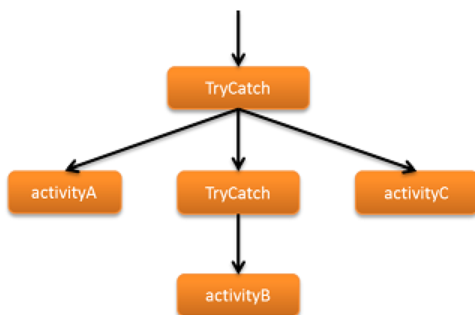
Receiving Notification of Canceled Tasks

When a task is completed in canceled state, the framework informs the workflow logic by throwing a `CancellationException`. When an activity completes in canceled state, a record is made in the history and the framework calls the appropriate `doCatch()` with a `CancellationException`. As shown in the previous example, when the payment processing task is canceled, the workflow receives a `CancellationException`.

An unhandled `CancellationException` is propagated up the execution branch just like any other exception. However, the `doCatch()` method will receive the `CancellationException` only if there is no other exception in the scope; other exceptions are prioritized higher than cancellation.

Nested TryCatchFinally

You may nest `TryCatchFinally`'s to suit your needs. Since each `TryCatchFinally` creates a new branch in the execution tree, you can create nested scopes. Exceptions in the parent scope will cause cancellation attempts of all tasks initiated by nested `TryCatchFinally`'s within it. However, exceptions in a nested `TryCatchFinally` don't automatically propagate to the parent. If you wish to propagate an exception from a nested `TryCatchFinally` to its containing `TryCatchFinally`, you should rethrow the exception in `doCatch()`. In other words, only unhandled exceptions are bubbled up, just like Java's `try`/`catch`. If you cancel a nested `TryCatchFinally` by calling the cancel method, the nested `TryCatchFinally` will be canceled but the containing `TryCatchFinally` will not automatically get canceled.



```
new TryCatch() {

  @Override
  protected void doTry() throws Throwable {
    activityA();

    new TryCatch() {
```

```
      @Override
      protected void doTry() throws Throwable {
        activityB();
      }

      @Override
      protected void doCatch(Throwable e) throws Throwable {
       reportError(e);
      }
    };

    activityC();
  }

  @Override
  protected void doCatch(Throwable e) throws Throwable {
    reportError(e);
  }
};
```

Retry Failed Activities

Activities sometimes fail for ephemeral reasons, such as a temporary loss of connectivity. At another time, the activity might succeed, so the appropriate way to handle activity failure is often to retry the activity, perhaps multiple times.

There are a variety of strategies for retrying activities; the best one depends on the details of your workflow. The strategies fall into three basic categories:

- The retry-until-success strategy simply keeps retrying the activity until it completes.
- The exponential retry strategy increases the time interval between retry attempts exponentially until the activity completes or the process reaches a specified stopping point, such as a maximum number of attempts.
- The custom retry strategy decides whether or how to retry the activity after each failed attempt.

The following sections describe how to implement these strategies. The example workflow workers all use a single activity, `unreliableActivity`, which randomly does one of following:

- Completes immediately
- Fails intentionally by exceeding the timeout value
- Fails intentionally by throwing `IllegalStateException`

For complete working code for these examples, see XYZ.

Retry-Until-Success Strategy

The simplest retry strategy is to keep retrying the activity each time it fails until it eventually succeeds. The basic pattern is:

1. Implement a nested `TryCatch` or `TryCatchFinally` class in your workflow's entry point method.
2. Execute the activity in `doTry`
3. If the activity fails, the framework calls `doCatch`, which runs the entry point method again.

4. Repeat Steps 2 - 3 until the activity completes successfully.

The following workflow implements the retry-until-success strategy. The workflow interface is implemented in `RetryActivityRecipeWorkflow` and has one method, `runUnreliableActivityTillSuccess`, which is the workflow's entry point. The workflow worker is implemented in `RetryActivityRecipeWorkflowImpl`, as follows:

```
public class RetryActivityRecipeWorkflowImpl implements RetryActivityRecipeWork
flow {
     ...
    @Override
    public void runUnreliableActivityTillSuccess() {

        final Settable<Boolean> retryActivity = new Settable<Boolean>();

        new TryCatch() {
            @Override
            protected void doTry() throws Throwable {
               Promise<Void> activityRanSuccessfully = client.unreliableActiv
ity();
              setRetryActivityToFalse(activityRanSuccessfully, retryActivity);

            }
            @Override
            protected void doCatch(Throwable e) throws Throwable {
                retryActivity.set(true);
            }
        };
        restartRunUnreliableActivityTillSuccess(retryActivity);
    }
    @Asynchronous
   private void setRetryActivityToFalse(Promise<Void> activityRanSuccessfully,
 Settable<Boolean> retryActivity) {
        retryActivity.set(false);
    }
    @Asynchronous
    private void restartRunUnreliableActivityTillSuccess(Settable<Boolean>
retryActivity) {
        if (retryActivity.get()) {
            runUnreliableActivityTillSuccess();
        }
    }
}
```

The workflow works as follows:

1. `runUnreliableActivityTillSuccess` creates a `Settable<Boolean>` object named `retryActivity` which is used to indicate whether the activity failed and should be retried. `Settable<T>` is derived from `Promise<T>` and works much the same way, but you set a `Settable<T>` object's value manually.
2. `runUnreliableActivityTillSuccess` implements an anonymous nested `TryCatch` class to handle any exceptions that are thrown by the `unreliableActivity` activity. For more discussion of how to handle exceptions thrown by asynchronous code, see Error Handling (p. 84).
3. `doTry` executes the `unreliableActivity` activity, which returns a `Promise<Void>` object named `waitFor`.

4. `doTry` calls the asynchronous `setRetryActivityToFalse` method, which has two parameters:
   - `activityRanSuccessfully` takes the `Promise<Void>` object returned by the `unreliableActivity` activity.
   - `retryActivity` takes the `retryActivity` object.

   If `unreliableActivity` completes, `activityRanSuccessfully` becomes ready and `setRetryActivityToFalse` sets `retryActivity` to false. Otherwise, `activityRanSuccessfully` never becomes ready and `setRetryActivityToFalse` does not execute.
5. If `unreliableActivity` throws an exception, the framework calls `doCatch` and passes it the exception object. `doCatch` sets `retryActivity` to true.
6. `runUnreliableActivityTillSuccess` calls the asynchronous `restartRunUnreliableActivityTillSuccess` method and passes it the `retryActivity` object. Because `retryActivity` is a `Promise<T>` type, `restartRunUnreliableActivityTillSuccess` defers execution until `retryActivity` is ready, which occurs after `TryCatch` completes.
7. When `retryActivity` is ready, `restartRunUnreliableActivityTillSuccess` extracts the value.
   - If the value is `false`, the retry succeeded. `restartRunUnreliableActivityTillSuccess` does nothing and the retry sequence terminates.
   - If the value is true, the retry failed. `restartRunUnreliableActivityTillSuccess` calls `runUnreliableActivityTillSuccess` to execute the activity again.
8. Steps 1 - 7 repeat until `unreliableActivity` completes.

Note

`doCatch` does not handle the exception; it simply sets the `retryActivity` object to true to indicate that the activity failed. The retry is handled by the asynchronous `restartRunUnreliableActivityTillSuccess` method, which defers execution until `TryCatch` completes. The reason for this approach is that, if you retry an activity in `doCatch`, you cannot cancel it. Retrying the activity in `restartRunUnreliableActivityTillSuccess` allows you to execute cancellable activities.

For a complete working example of this workflow, see XYZ.

Exponential Retry Strategy

With the exponential retry strategy, the framework executes a failed activity again after a specified period of time, N seconds. If that attempt fails the framework executes the activity again after 2N seconds, and then 4N seconds and so on. Because the wait time can get quite large, you typically stop the retry attempts at some point rather than continuing indefinitely.

The framework provides three ways to implement an exponential retry strategy:

- The `@ExponentialRetry` annotation is the simplest approach, but you must set the retry configuration options at compile time.
- The `RetryDecorator` class allows you to set retry configuration at run time and change it as needed.
- The `AsyncRetryingExecutor` class allows you to set retry configuration at run time and change it as needed. In addition, the framework calls a user-implemented `AsyncRunnable.run` method to run each retry attempt.

All approaches support the following configuration options, where time values are in seconds:

- The initial retry wait time.
- The back-off coefficient, which is used to compute the retry intervals, as follows:

```
retryInterval = initialRetryIntervalSeconds * Math.pow(backoffCoefficient,
numberOfTries - 2)
```

The default value is 2.0.

- The maximum number of retry attempts. The default value is unlimited.
- The maximum retry interval. The default value is unlimited.
- The expiration time. Retry attempts stop when the total duration of the process exceeds this value. The default value is unlimited.
- The exceptions that will trigger the retry process. By default, every exception triggers the retry process.
- The exceptions that will not trigger a retry attempt. By default, no exceptions are excluded.

The following sections describe the various ways that you can implement an exponential retry strategy. For complete working code for the examples, see XYZ.

Exponential Retry with @ExponentialRetry

The simplest way to implement an exponential retry strategy for an activity is to apply an `@ExponentialRetry` annotation to the activity in the interface definition. If the activity fails, the framework handles the retry process automatically, based on the specified option values. The basic pattern is:

1. Apply `@ExponentialRetry` to the appropriate activities and specify the retry configuration.
2. If an annotated activity fails, the framework automatically retrys the activity according to the configuration specified by the annotation's arguments.

The `ExponentialRetryAnnotationWorkflow` workflow worker implements the exponential retry strategy by using an `@ExponentialRetry` annotation. It uses an `unreliableActivity` activity whose interface definition is implemented in `ExponentialRetryAnnotationActivities`, as follows:

```
@Activities(version = "1.0")
@ActivityRegistrationOptions(defaultTaskScheduleToStartTimeoutSeconds = 30,
defaultTaskStartToCloseTimeoutSeconds = 30)
public interface ExponentialRetryAnnotationActivities {

    @ExponentialRetry(initialRetryIntervalSeconds = 5, maximumAttempts = 5,
exceptionsToRetry = IllegalStateException.class)
    public void unreliableActivity();
}
```

The `@ExponentialRetry` options specify the following strategy:

- Retry only if the activity throws `IllegalStateException`.
- Use an initial wait time of 5 seconds.
- No more than 5 retry attempts.

The workflow interface is implemented in `RetryWorkflow` and has one method, `process`, which is the workflow's entry point. The workflow worker is implemented in `ExponentialRetryAnnotationWorkflowImpl`, as follows:

```
public class ExponentialRetryAnnotationWorkflowImpl implements RetryWorkflow {
```

```
    ...
    public void process() {
        handleUnreliableActivity();
    }
    public void handleUnreliableActivity() {
        client.unreliableActivity();
    }
}
```

The workflow works as follows:

1. `process` runs the synchronous `handleUnreliableActivity` method.
2. `handleUnreliableActivity` executes the `unreliableActivity` activity.

If the activity fails by throwing `IllegalStateException`, the framework automatically runs the retry strategy specified in `ExponentialRetryAnnotationActivities`.

Exponential Retry with the RetryDecorator Class

`@ExponentialRetry` is simple to use. However, the configuration is static and set at compile time, so the framework uses the same retry strategy every time the activity fails. You can implement a more flexible exponential retry strategy by using the `RetryDecorator` class, which allows you to specify the configuration at run time and change it as needed. The basic pattern is:

1. Create and configure an `ExponentialRetryPolicy` object that specifies the retry configuration.
2. Create a `RetryDecorator` object and pass the `ExponentialRetryPolicy` object from Step 1 to the constructor.
3. Apply the decorator object to the activity by passing the activity client's class name to the `RetryDecorator` object's decorate method.
4. Execute the activity.

If the activity fails, the framework retries the activity according to the `ExponentialRetryPolicy` object's configuration. You can change the retry configuration as needed by modifying this object.

> **Note**
> The `@ExponentialRetry` annotation and the `RetryDecorator` class are mutually exclusive. You cannot use `RetryDecorator` to dynamically override a retry policy specified by an `@ExponentialRetry` annotation.

The following workflow implementation shows how to use the `RetryDecorator` class to implement an exponential retry strategy. It uses an `unreliableActivity` activity that does not have an `@ExponentialRetry` annotation. The workflow interface is implemented in `RetryWorkflow` and has one method, `process`, which is the workflow's entry point. The workflow worker is implemented in `DecoratorRetryWorkflowImpl`, as follows:

```
public class DecoratorRetryWorkflowImpl implements RetryWorkflow {
    ...
    public void process() {
        long initialRetryIntervalSeconds = 5;
        int maximumAttempts = 5;
        ExponentialRetryPolicy retryPolicy = new ExponentialRetryPolicy(ini
tialRetryIntervalSeconds).withMaximumAttempts(maximumAttempts);
```

```
        Decorator retryDecorator = new RetryDecorator(retryPolicy);
        client = retryDecorator.decorate(RetryActivitiesClient.class, client);

        handleUnreliableActivity();
    }

    public void handleUnreliableActivity() {
        client.unreliableActivity();
    }
}
```

The workflow works as follows:

1. `process` creates and configures an `ExponentialRetryPolicy` object by:
   - Passing the initial retry interval to the constructor.
   - Calling the object's `withMaximumAttempts` method to set the maximum number of attempts to 5. `ExponentialRetryPolicy` exposes other `withXYZ` objects that you can use to specify other configuration options.
2. `process` creates a `RetryDecorator` object named `retryDecorator` and passes the `ExponentialRetryPolicy` object from Step 1 to the constructor.
3. `process` applies the decorator to the activity by calling the `retryDecorator.decorate` method and passing it the activity client's class name.
4. `handleUnreliableActivity` executes the activity.

If the activity fails, the framework retries it according to the configuration specified in Step 1.

Note
Several of the `ExponentialRetryPolicy` class's `withXYZ` methods have a corresponding `setXYZ` method that you can call to modify the corresponding configuration option at any time: `setBackoffCoefficient`, `setMaximumAttempts`, `setMaximumRetryIntervalSeconds`, and `setMaximumRetryExpirationIntervalSeconds`.

Exponential Retry with the AsyncRetryingExecutor Class

The `RetryDecorator` class provides more flexibility in configuring the retry process than `@ExponentialRetry`, but the framework still runs the retry attempts automatically, based on the `ExponentialRetryPolicy` object's current configuration. A more flexible approach is to use the `AsyncRetryingExecutor` class. In addition to allowing you to configure the retry process at run time, the framework calls a user-implemented `AsyncRunnable.run` method to run each retry attempt instead of simply executing the activity.

The basic pattern is:

1. Create and configure an `ExponentialRetryPolicy` object to specify the retry configuration.
2. Create an `AsyncRetryingExecutor` object, and pass it the `ExponentialRetryPolicy` object and an instance of the workflow clock.
3. Implement an anonymous nested `TryCatch` or `TryCatchFinally` class.
4. Implement an anonymous `AsyncRunnable` class and override the `run` method to implement custom code for running the activity.
5. Override `doTry` to call the `AsyncRetryingExecutor` object's `execute` method and pass it the `AsyncRunnable` class from Step 4. The `AsyncRetryingExecutor` object calls `AsyncRunnable.run` to run the activity.

6. If the activity fails, the `AsyncRetryingExecutor` object calls the `AsyncRunnable.run` method again, according to the retry policy specified in Step 1.

The following workflow shows how to use the `AsyncRetryingExecutor` class to implement an exponential retry strategy. It uses the same `unreliableActivity` activity as the `DecoratorRetryWorkflow` workflow discussed earlier. The workflow interface is implemented in `RetryWorkflow` and has one method, `process`, which is the workflow's entry point. The workflow worker is implemented in `AsyncExecutorRetryWorkflowImpl`, as follows:

```
public class AsyncExecutorRetryWorkflowImpl implements RetryWorkflow {
    private final RetryActivitiesClient client = new RetryActivitiesClientImpl();

    private final DecisionContextProvider contextProvider = new DecisionContex
tProviderImpl();
    private final WorkflowClock clock = contextProvider.getDecisionContext().get
WorkflowClock();

    public void process() {
        long initialRetryIntervalSeconds = 5;
        int maximumAttempts = 5;
       handleUnreliableActivity(initialRetryIntervalSeconds, maximumAttempts);

    }
    public void handleUnreliableActivity(long initialRetryIntervalSeconds, int
 maximumAttempts) {

        ExponentialRetryPolicy retryPolicy = new ExponentialRetryPolicy(ini
tialRetryIntervalSeconds).withMaximumAttempts(maximumAttempts);
        final AsyncExecutor executor = new AsyncRetryingExecutor(retryPolicy,
clock);

        new TryCatch() {
            @Override
            protected void doTry() throws Throwable {
                executor.execute(new AsyncRunnable() {
                    @Override
                    public void run() throws Throwable {
                        client.unreliableActivity();
                    }
                });
            }
            @Override
            protected void doCatch(Throwable e) throws Throwable {
            }
        };
    }
}
```

The workflow works as follows:

1. `process` calls the `handleUnreliableActivity` method and passes it the configuration settings.
2. `handleUnreliableActivity` uses the configuration settings from Step 1 to create an `ExponentialRetryPolicy` object, `retryPolicy`.

3. handleUnreliableActivity creates an AsyncRetryExecutor object, executor, and passes the ExponentialRetryPolicy object from Step 2 and an instance of the workflow clock to the constructor
4. handleUnreliableActivity implements an anonymous nested TryCatch class and overrides the doTry and doCatch methods to run the retry attempts and handle any exceptions.
5. doTry creates an anonymous AsyncRunnable class and overrides the run method to implement custom code to execute unreliableActivity. For simplicity, run just executes the activity, but you can implement more sophisticated approaches as appropriate.
6. doTry calls executor.execute and passes it the AsyncRunnable object. execute calls the AsyncRunnable object's run method to run the activity.
7. If the activity fails, executor calls run again, according to the retryPolicy object configuration.

For more discussion of how to use the TryCatch class to handle errors, see AWS Flow Framework for Java Exceptions (p. 117).

Custom Retry Strategy

The most flexible approach to retrying failed activities is a custom strategy, which recursively calls an asynchronous method that runs the retry attempt, much like the retry-until-success strategy. However, instead of simply running the activity again, you implement custom logic that decides whether and how to run each successive retry attempt. The basic pattern is:

1. Create a Settable<T> status object, which is used to indicate whether the activity failed.
2. Implement a nested TryCatch or TryCatchFinally class.
3. doTry executes the activity.
4. If the activity fails, doCatch sets the status object to indicate that the activity failed.
5. Call an asynchronous failure handling method and pass it the status object. The method defers execution until TryCatch or TryCatchFinally completes.
6. The failure handling method decides whether to retry the activity, and if so, when.

The following workflow shows how to implement a custom retry strategy. It uses the same unreliableActivity activity as the DecoratorRetryWorkflow and AsyncExecutorRetryWorkflow workflows. The workflow interface is implemented in RetryWorkflow and has one method, process, which is the workflow's entry point. The workflow worker is implemented in CustomLogicRetryWorkflowImpl, as follows:

```
public class CustomLogicRetryWorkflowImpl implements RetryWorkflow {
    ...
    public void process() {
        callActivityWithRetry();
    }
    @Asynchronous
    public void callActivityWithRetry() {
        final Settable<Throwable> failure = new Settable<Throwable>();
        new TryCatchFinally() {
            protected void doTry() throws Throwable {
                client.unreliableActivity();
            }
            protected void doCatch(Throwable e) {
                failure.set(e);
            }
            protected void doFinally() throws Throwable {
```

```
                if (!failure.isReady()) {
                    failure.set(null);
                }
            }
        };
        retryOnFailure(failure);
    }
    @Asynchronous
    private void retryOnFailure(Promise<Throwable> failureP) {
        Throwable failure = failureP.get();
        if (failure != null && shouldRetry(failure)) {
            callActivityWithRetry();
        }
    }
    protected Boolean shouldRetry(Throwable e) {
        //custom logic to decide to retry the activity or not
        return true;
    }
}
```

The workflow works as follows:

1. `process` calls the asynchronous `callActivityWithRetry` method.
2. `callActivityWithRetry` creates a `Settable<Throwable>` object named failure which is used to indicate whether the activity has failed. `Settable<T>` is derived from `Promise<T>` and works much the same way, but you set a `Settable<T>` object's value manually.
3. `callActivityWithRetry` implements an anonymous nested `TryCatchFinally` class to handle any exceptions that are thrown by `unreliableActivity`. For more discussion of how to handle exceptions thrown by asynchronous code, see AWS Flow Framework for Java Exceptions (p. 117).
4. `doTry` executes `unreliableActivity`.
5. If `unreliableActivity` throws an exception, the framework calls `doCatch` and passes it the exception object. `doCatch` sets `failure` to the exception object, which indicates that the activity failed and puts the object in a ready state.
6. `doFinally` checks whether `failure` is ready, which will be true only if `failure` was set by `doCatch`.
   - If `failure` is ready, `doFinally` does nothing.
   - If `failure` is not ready, the activity completed and `doFinally` sets failure to `null`.
7. `callActivityWithRetry` calls the asynchronous `retryOnFailure` method and passes it failure. Because failure is a `Settable<T>` type, `callActivityWithRetry` defers execution until failure is ready, which occurs after `TryCatchFinally` completes.
8. `retryOnFailure` gets the value from failure.
   - If failure is set to null, the retry attempt was successful. `retryOnFailure` does nothing, which terminates the retry process.
   - If failure is set to an exception object and `shouldRetry` returns true, `retryOnFailure` calls `callActivityWithRetry` to retry the activity.

     `shouldRetry` implements custom logic to decide whether to retry a failed activity. For simplicity, `shouldRetry` always returns `true` and `retryOnFailure` executes the activity immediately, but you can implement more sophisticated logic as needed.
9. Steps 2 - 8 repeat until `unreliableActivity` completes or `shouldRetry` decides to stop the process.

Note

doCatch does not handle the retry process; it simply sets failure to indicate that the activity failed. The retry process is handled by the asynchronous retryOnFailure method, which defers execution until TryCatch completes. The reason for this approach is that, if you retry an activity in doCatch, you cannot cancel it. Retrying the activity in retryOnFailure allows you to execute cancellable activities.

Daemon Tasks

The AWS Flow Framework for Java allows the marking of certain tasks as daemon. This allows you to create tasks that do some background work that should get canceled when all other work is done. For example, a health monitoring task should be canceled when the rest of the workflow is complete. You can accomplish this by setting the daemon flag on an asynchronous method or an instance of TryCatchFinally. In the following example, the asynchronous method monitorHealth() is marked as daemon.

```
public class MyWorkflowImpl implements MyWorkflow {
    MyActivitiesClient activitiesClient = new MyActivitiesClientImpl();

    @Override
    public void startMyWF(int a, String b) {
        activitiesClient.doUsefulWorkActivity();
        monitorHealth();
    }

    @Asynchronous(daemon=true)
    void monitorHealth(Promise<?>... waitFor) {
        activitiesClient.monitoringActivity();
    }
}
```

In the above example, when doUsefulWorkActivity completes, monitoringHealth will be automatically canceled. This will in turn cancel the whole execution branch rooted at this asynchronous method. The semantics of cancellation are the same as described in TryCatchFinally. Similarly, you can mark a TryCatchFinally daemon by passing a Boolean flag to the constructor.

```
public class MyWorkflowImpl implements MyWorkflow {
    MyActivitiesClient activitiesClient = new MyActivitiesClientImpl();

    @Override
    public void startMyWF(int a, String b) {
        activitiesClient.doUsefulWorkActivity();
        new TryFinally(true) {
            @Override
            protected void doTry() throws Throwable {
                activitiesClient.monitoringActivity();
            }

            @Override
            protected void doFinally() throws Throwable {
                // clean up
            }
        };
```

```
    }
}
```

A daemon task started within a `TryCatchFinally` is scoped to the context it is created in—that is, it will be scoped to either the `doTry()`, `doCatch()`, or `doFinally()` methods. For example, in the following example the startMonitoring asynchronous method is marked daemon and called from `doTry()`. The task created for it will be canceled as soon as the other tasks (`doUsefulWorkActivity` in this case) started within `doTry()` are complete.

```
public class MyWorkflowImpl implements MyWorkflow {
    MyActivitiesClient activitiesClient = new MyActivitiesClientImpl();

    @Override
    public void startMyWF(int a, String b) {
        new TryFinally() {
            @Override
            protected void doTry() throws Throwable {
                activitiesClient.doUsefulWorkActivity();
                startMonitoring();
            }

            @Override
            protected void doFinally() throws Throwable {
                // Clean up
            }
        };
    }

    @Asynchronous(daemon = true)
    void startMonitoring(){
     activitiesClient.monitoringActivity();
    }
}
```

AWS Flow Framework for Java Replay Behavior

This topic discusses examples of replay behavior, using the examples in the Introduction (p. 1) section. Both synchronous (p. 101) and asynchronous (p. 103) scenarios are discussed.

Example 1: Synchronous Replay

For an example of how replay works in a synchronous workflow, modify the HelloWorldWorkflow (p. 8) workflow and activity implementations by adding `println` calls within their respective implementations, as follows:

```
public class GreeterWorkflowImpl implements GreeterWorkflow {
...
   public void greet() {
      System.out.println("greet executes");
      Promise<String> name = operations.getName();
      System.out.println("client.getName returns");
```

```
        Promise<String> greeting = operations.getGreeting(name);
        System.out.println("client.greeting returns");
        operations.say(greeting);
        System.out.println("client.say returns");
    }
}
**************
public class GreeterActivitiesImpl implements GreeterActivities {
    public String getName() {
        System.out.println("activity.getName completes");
        return "World";
    }

    public String getGreeting(String name) {
        System.out.println("activity.getGreeting completes");
        return "Hello " + name + "!";
    }

    public void say(String what) {
        System.out.println(what);
    }
}
```

For details about the code, see HelloWorldWorkflow Application (p. 8). The following is an edited version of the output, with comments that indicate the start of each replay episode.

```
//Episode 1
greet executes
client.getName returns
client.greeting returns
client.say returns

activity.getName completes
//Episode 2
greet executes
client.getName returns
client.greeting returns
client.say returns

activity.getGreeting completes
//Episode 3
greet executes
client.getName returns
client.greeting returns
client.say returns

Hello World! //say completes
//Episode 4
greet executes
client.getName returns
client.greeting returns
client.say returns
```

The replay process for this example works as follows:

- The first episode schedules the `getName` activity task, which has no dependencies.

- The second episode schedules the `getGreeting` activity task, which depends on `getName`.
- The third episode schedules the `say` activity task, which depends on `getGreeting`.
- The final episode schedules no additional tasks and finds no uncompleted activities, which terminates the workflow execution.

> **Note**
> The three activities client methods are called once for each episode. However, only one of those calls results in an activity task, so each task is performed only once.

Example 2: Asynchronous Replay

Similarly to the synchronous replay example (p. 101), you can modify HelloWorldWorkflowAsync Application (p. 20) to see how an asynchronous replay works. It produces the following output:

```
//Episode 1
greet executes
client.name returns
workflow.getGreeting returns
client.say returns

activity.getName completes
//Episode 2
greet executes
client.name returns
workflow.getGreeting returns
client.say returns
workflow.getGreeting completes

Hello World! //say completes
//Episode 3
greet executes
client.name returns
workflow.getGreeting returns
client.say returns
workflow.getGreeting completes
```

HelloWorldAsync uses three replay episodes because there are only two activities. The `getGreeting` activity was replaced by the *getGreeting* asynchronous workflow method, which does not initiate a replay episode when it completes.

The first episode does not call `getGreeting`, because it depends on the completion of the *name* activity. However, after *getName* completes, replay calls *getGreeting* once for each succeeding episode.

Under the Hood

Topics

- Task (p. 104)
- Order of Execution (p. 105)
- Workflow Execution (p. 106)
- Nondeterminism (p. 108)

Task

The underlying primitive that the AWS Flow Framework for Java uses to manage the execution of asynchronous code is the `Task` class. An object of type `Task` represents work that has to be performed asynchronously. When you call an asynchronous method, the framework creates a `Task` to execute the code in that method and puts it in a list for execution at a later time. Similarly, when you invoke an `Activity`, a `Task` is created for it. The method call returns after this, usually returning a `Promise<T>` as the future result of the call.

The `Task` class is public and may be used directly. For example, we can rewrite the Hello World example to use a `Task` instead of an asynchronous method.

```
@Override
public void startHelloWorld(){
       final Promise<String> greeting = client.getName();
        new Task(greeting) {
        @Override
        protected void doExecute() throws Throwable {
         client.printGreeting("Hello " + greeting.get() +"!");
        }
    };
}
```

The framework calls the `doExecute()` method when all the `Promise`s passed to the constructor of the `Task` become ready. For more details about the `Task` class, see the AWS Java SDK documentation.

The framework also includes a class called `Functor` which represents a `Task` that is also a `Promise<T>`. The `Functor` object becomes ready when the `Task` completes. In the following example, a `Functor` is created to get the greeting message:

```
Promise<String> greeting = new Functor<String>() {
    @Override
    protected Promise<String> doExecute() throws Throwable {
        return client.getGreeting();
    }
};
client.printGreeting(greeting);
```

Order of Execution

Tasks become eligible for execution only when all `Promise<T>` typed parameters, passed to the corresponding asynchronous method or activity, become ready. A `Task` that is ready for execution is logically moved to a ready queue. In other words, it is scheduled for execution. The worker class executes the task by invoking the code that you wrote in the body of the asynchronous method, or by scheduling an activity task in Amazon Simple Workflow Service (AWS) in case of an activity method.

As tasks execute and produce results, they cause other tasks to become ready and the execution of the program keeps moving forward. The way the framework executes tasks is important to understand the order in which your asynchronous code executes. Code that appears sequentially in your program may not actually execute in that order.

```
Promise<String> name = getUserName();
printHelloName(name);
printHelloWorld();
System.out.println("Hello, Amazon!");

@Asynchronous
private Promise<String> getUserName(){
 return Promise.asPromise("Bob");
}
@Asynchronous
private void printHelloName(Promise<String> name){
 System.out.println("Hello, " + name.get() + "!");
}
@Asynchronous
private void printHelloWorld(){
 System.out.println("Hello, World!");
}
```

The code in the listing above will print the following:

```
Hello, Amazon!
Hello, World!
Hello, Bob
```

This may not be what you expected but can be easily explained by thinking through how the tasks for the asynchronous methods were executed:

1. The call to `getUserName` creates a `Task`. Let's call it `Task1`. Since `getUserName` does not take any parameters, `Task1` is immediately put in the ready queue.
2. Next, the call to `printHelloName` creates a `Task` that needs to wait for the result of `getUserName`. Let's call it `Task2`. Since the requisite value isn't ready yet, `Task2` is put in the wait list.
3. Then a task for `printHelloWorld` is created and added to the ready queue. Let's call it `Task3`.
4. The `println` statement then prints "Hello, Amazon!" to the console.
5. At this point, `Task1` and `Task3` are in the ready queue and `Task2` is in the wait list.
6. The worker executes `Task1`, and its result makes `Task2` ready. `Task2` gets added to ready queue behind `Task3`.
7. `Task3` and `Task2` are then executed in that order.

The execution of activities follows the same pattern. When you call a method on the activity client, it creates a `Task` that, upon execution, schedules an activity in Amazon SWF.

The framework relies on features like code generation and dynamic proxies to inject the logic for converting method calls to activity invocations and asynchronous tasks in your program.

Workflow Execution

The execution of the workflow implementation is also managed by the worker class. When you call a method on the workflow client, it calls Amazon SWF to create a workflow instance. The tasks in Amazon SWF should not be confused with the tasks in the framework. A task in Amazon SWF is either an activity task or a decision task. The execution of activity tasks is simple. The activity worker class receives activity tasks from Amazon SWF, invokes the appropriate activity method in your implementation, and returns the result to Amazon SWF.

The execution of decision tasks is more involved. The workflow worker receives decision tasks from Amazon SWF. A decision task is effectively a request asking the workflow logic what to do next. The first decision task is generated for a workflow instance when it is started through the workflow client. Upon receiving this decision task, the framework starts executing the code in the workflow method annotated with `@Execute`. This method executes the coordination logic that schedules activities. When the state of the workflow instance changes—for example, when an activity completes—further decision tasks get scheduled. At this point, the workflow logic can decide to take an action based on the result of the activity; for example, it may decide to schedule another activity.

The framework hides all these details from the developer by seamlessly translating decision tasks to the workflow logic. From a developer's point of view, the code looks just like a regular program. Under the covers, the framework maps it to calls to Amazon SWF and decision tasks using the history maintained by Amazon SWF. When a decision task arrives, the framework replays the program execution plugging in the results of the activities completed so far. Asynchronous methods and activities that were waiting for these results get unblocked, and the program execution moves forward.

The execution of the example image processing workflow and the corresponding history is shown in the following table.

Execution of thumbnail workflow

Workflow program execution	History maintained by Amazon SWF
Initial execution	

Workflow program execution	History maintained by Amazon SWF
1. Dispatch loop 2. *getImageUrls* 3. downloadImage 4. createThumbnail (task in wait queue) 5. uploadImage (task in wait queue) 6. <next iteration of the loop>	1. Workflow instance started, id="1" 2. downloadImage scheduled
Replay	
1. Dispatch loop 2. *getImageUrls* 3. *downloadImage image* path="foo" 4. createThumbnail 5. uploadImage (task in wait queue) 6. <next iteration of the loop>	1. Workflow instance started, id="1" 2. downloadImage scheduled 3. downloadImage completed, return="foo" 4. createThumbnail scheduled
Replay	
1. Dispatch loop 2. *getImageUrls* 3. *downloadImage image* path="foo" 4. *createThumbnail* thumbnail path="bar" 5. uploadImage 6. <next iteration of the loop>	1. Workflow instance started, id="1" 2. downloadImage scheduled 3. downloadImage completed, return="foo" 4. createThumbnail scheduled 5. createThumbnail completed, return="bar" 6. uploadImage scheduled
Replay	
1. Dispatch loop 2. *getImageUrls* 3. *downloadImage image* path="foo" 4. *createThumbnail* thumbnail path="bar" 5. *uploadImage* 6. <next iteration of the loop>	1. Workflow instance started, id="1" 2. downloadImage scheduled 3. downloadImage completed, return="foo" 4. createThumbnail scheduled 5. createThumbnail completed, return="bar" 6. uploadImage scheduled 7. uploadImage completed ...

When a call to `processImage` is made, the framework creates a new workflow instance in Amazon SWF. This is a durable record of the workflow instance being started. The program executes until the call to the `downloadImage` activity, which asks Amazon SWF to schedule an activity. The workflow executes further and creates tasks for subsequent activities, but they cannot be executed until the `downloadImage` activity completes; hence, this episode of replay ends. Amazon SWF dispatches the task for `downloadImage` activity for execution, and once it is completed, a record is made in the history along with the result. The workflow is now ready to move forward and a decision task is generated by Amazon

SWF. The framework receives the decision task and replays the workflow plugging in the result of the downloaded image as recorded in the history. This unblocks the task for `createThumbnail`, and the execution of the program continues farther by scheduling the `createThumbnail` activity task in Amazon SWF. The same process repeats for `uploadImage`. The execution of the program continues this way until the workflow has processed all images and there are no pending tasks. Since no execution state is stored locally, each decision task may be potentially executed on a different machine. This allows you to easily write programs that are fault tolerant and easily scalable.

Nondeterminism

Since the framework relies on replay, it is important that the orchestration code (all workflow code with the exception of activity implementations) be deterministic. For example, the control flow in your program should not depend on a random number or the current time. Since these things will change between invocations, the replay may not follow the same path through the orchestration logic. This will lead to unexpected results or errors. The framework provides a `WorkflowClock` that you can use to get the current time in a deterministic way. See the section on Execution Context (p. 66) for more details.

Note

Incorrect Spring wiring of workflow implementation objects can also lead to nondeterminism. Workflow implementation beans as well as beans that they depend on must be in the workflow scope (`WorkflowScope`). For example, wiring a workflow implementation bean to a bean that keeps state and is in the global context will result in unexpected behavior. See the Spring Integration (p. 75) section for more details.

Troubleshooting and Debugging Tips

Topics

- Compilation Errors (p. 109)
- Unknown Resource Fault (p. 109)
- Exceptions When Calling get() on a Promise (p. 110)
- Non Deterministic Workflows (p. 110)
- Problems Due to Versioning (p. 110)
- Troubleshooting and Debugging a Workflow Execution (p. 110)
- Lost Tasks (p. 112)

This section describes some common pitfalls that you might run into while developing workflows using AWS Flow Framework for Java. It also provides some tips to help you diagnose and debug problems.

Compilation Errors

If you are using the AspectJ compile time weaving option, you may run into compile time errors in which the compiler is not able to find the generated client classes for your workflow and activities. The likely cause of such compilation errors is that the AspectJ builder ignored the generated clients during compilation. You can fix this issue by removing AspectJ capability from the project and reenabling it. Note that you will need to do this every time your workflow or activities interfaces change. Because of this issue, we recommend that you use the load time weaving option instead. See the section Setting up the Development Environment (p. 2) for more details.

Unknown Resource Fault

Amazon SWF returns unknown resource fault when you try to perform an operation on a resource that is not available. The common causes for this fault are:

- You configure a worker with a domain that does not exist. To fix this, first register the domain using the Amazon SWF console or the Amazon SWF service API.

- You try to create workflow execution or activity tasks of types that have not been registered. This can happen if you try to create the workflow execution before the workers have been run. Since workers register their types when they are run for the first time, you must run them at least once before attempting to start executions (or manually register the types using the Console or the service API). Note that once types have been registered, you can create executions even if no worker is running.
- A worker attempts to complete a task that has already timed out. For example, if a worker takes too long to process a task and exceeds a timeout, it will get an UnknownResource fault when it attempts to complete or fail the task. The AWS Flow Framework workers will continue to poll Amazon SWF and process additional tasks. However, you should consider adjusting the timeout. Adjusting the timeout requires that you register a new version of the activity type.

Exceptions When Calling get() on a Promise

Unlike Java Future, `Promise` is a non-blocking construct and calling `get()` on a `Promise` that is not ready yet will throw an exception instead of blocking. The correct way to use a `Promise` is to pass it to an asynchronous method (or a task) and access its value in the asynchronous method. AWS Flow Framework for Java ensures that an asynchronous method is called only when all `Promise` arguments passed to it have become ready. If you believe your code is correct or if you run into this while running one of the AWS Flow Framework samples, then it is most likely due to AspectJ not being properly configured. For details, see the section Setting up the Development Environment (p. 2).

Non Deterministic Workflows

As described in the section Nondeterminism (p. 108), the implementation of your workflow must be deterministic. Some common mistakes that can lead to nondeterminism are use of system clock, use of random numbers, and generation of GUIDs. Since these constructs may return different values at different times, the control flow of your workflow may take different paths each time it is executed (see the sections AWS Flow Framework Basic Concepts: Distributed Execution (p. 32) and Under the Hood (p. 104) for details). If the framework detects nondeterminism while executing the workflow, an exception will be thrown.

Problems Due to Versioning

When you implement a new version of your workflow or activity—for instance, when you add a new feature—you should increase the version of the type by using the appropriate annotation: `@Workflow`, `@Activites`, or `@Activity`. When new versions of a workflow are deployed, often times you will have executions of the existing version that are already running. Therefore, you need to make sure that workers with the appropriate version of your workflow and activities get the tasks. You can accomplish this by using a different set of task lists for each version. For example, you can append the version number to the name of the task list. This ensures that tasks belonging to different versions of the workflow and activities are assigned to the appropriate workers.

Troubleshooting and Debugging a Workflow Execution

The first step in troubleshooting a workflow execution is to use the Amazon SWF console to look at the workflow history. The workflow history is a complete and authoritative record of all the events that changed the execution state of the workflow execution. This history is maintained by Amazon SWF and is invaluable

for diagnosing problems. The Amazon SWF console enables you to search for workflow executions and drill down into individual history events.

AWS Flow Framework provides a `WorkflowReplayer` class that you can use to replay a workflow execution locally and debug it. Using this class, you can debug closed and running workflow executions. `WorkflowReplayer` relies on the history stored in Amazon SWF to perform the replay. You can point it to a workflow execution in your Amazon SWF account or provide it with the history events (for example, you can retrieve the history from Amazon SWF and serialize it locally for later use). When you replay a workflow execution using the `WorkflowReplayer`, it does not impact the workflow execution running in your account. The replay is done completely on the client. You can debug the workflow, create breakpoints, and step into code using your debugging tools as usual. If you are using Eclipse, consider adding step filters to filter AWS Flow Framework packages.

For example, the following code snippet can be used to replay a workflow execution:

```
 String workflowId = "testWorkflow";
 String runId = "<run id>";
 Class<HelloWorldImpl> workflowImplementationType = HelloWorldImpl.class;
 WorkflowExecution workflowExecution = new WorkflowExecution();
 workflowExecution.setWorkflowId(workflowId);
 workflowExecution.setRunId(runId);

 WorkflowReplayer<HelloWorldImpl> replayer = new WorkflowReplayer>HelloWorldIm
pl>(swfService, domain, workflowExecution,
     workflowImplementationType);

 System.out.println("Beginning workflow replay for " + workflowExecution);
 Object workflow = replayer.loadWorkflow();
 System.out.println("Workflow implementation object:");
 System.out.println(workflow);
 System.out.println("Done workflow replay for " + workflowExecution);
```

AWS Flow Framework also allows you to get an asynchronous thread dump of your workflow execution. This thread dump gives you the call stacks of all open asynchronous tasks. This information can be useful to determine which tasks in the execution are pending and possibly stuck. For example:

```
String workflowId = "testWorkflow";
String runId = "<run id>";
Class<HelloWorldImpl> workflowImplementationType = HelloWorldImpl.class;
WorkflowExecution workflowExecution = new WorkflowExecution();
workflowExecution.setWorkflowId(workflowId);
workflowExecution.setRunId(runId);

WorkflowReplayer>HelloWorldImpl> replayer = new WorkflowReplayer>HelloWorldIm
pl>(swfService, domain, workflowExecution,
    workflowImplementationType);

try {
  String flowThreadDump = replayer.getAsynchronousThreadDumpAsString();
  System.out.println("Workflow asynchronous thread dump:");
  System.out.println(flowThreadDump);
}
catch (WorkflowException e) {
  System.out.println("No asynchronous thread dump available as workflow has
```

```
failed: " + e);
}
```

Lost Tasks

Sometimes you may shut down workers and start new ones in quick succession only to discover that tasks get delivered to the old workers. This can happen due to race conditions in the system, which is distributed across several processes. The problem can also appear when you are running unit tests in a tight loop. Stopping a test in Eclipse can also sometimes cause this because shutdown handlers may not get called.

In order to make sure that the problem is in fact due to old workers getting tasks, you should look at the workflow history to determine which process received the task that you expected the new worker to receive. For example, the `DecisionTaskStarted` event in history contains the identity of the workflow worker that received the task. The id used by the Flow Framework is of the form: {*processId*}@{*host name*}. For instance, following are the details of the `DecisionTaskStarted` event in the Amazon SWF console for a sample execution:

Event Timestamp	Mon Feb 20 11:52:40 GMT-800 2012
Identity	2276@ip-0A6C1DF5
Scheduled Event Id	33

In order to avoid this situation, use different task lists for each test. Also, consider adding a delay between shutting down old workers and starting new ones.

AWS Flow Framework for Java Annotations

Topics

- @Workflow (p. 113)
- @Execute (p. 114)
- @WorkflowRegistrationOptions (p. 114)
- @SkipRegistration (p. 115)
- @Signal (p. 115)
- @GetState (p. 115)
- @Activities (p. 115)
- @Activity (p. 115)
- @ActivityRegistrationOptions (p. 116)
- @ManualActivityCompletion (p. 116)
- @Asynchronous (p. 116)
- @ExponentialRetry (p. 117)
- @Wait and @NoWait (p. 117)

@Workflow

This annotation can be used on an interface to declare a workflow type. An interface annotated with this annotation should contain exactly one method with the `@Execute` annotation. An interface cannot have both `@Workflow` and `@Activities` annotations.

The following parameters can be specified on this annotation:

`dataConverter`
Specifies the type of the `DataConverter` to use for serializing/deserializing data when sending requests to and receiving results from workflow executions of this workflow type. Set to `NullDataConverter` by default, which indicates that the `JsonDataConverter` should be used.

@Execute

When used on a method in an interface annotated with the `@Workflow` annotation, identifies the entry point of the workflow. The annotation can be used on only one method in the interface.

The following parameters can be specified on this annotation:

`Name`
Specifies the name of the workflow type. If not set, the name will be defaulted to {*prefix*}{*name*}, where {*prefix*} is the name of the workflow interface followed by a '.' and {*name*} is the name of the `@Execute` method.

`Version`
Specifies the version of the workflow type.

@WorkflowRegistrationOptions

When used on an interface annotated with the `@Workflow` annotation, provides default settings used to register the workflow type with Amazon SWF. One of `@WorkflowRegistrationOptions` and `@SkipRegistrationOptions` annotations must be used on an interface annotated with `@Workflow`, but not both.

The following parameters can be specified on this annotation:

Description
An optional textual description of the workflow type.

`defaultExecutionStartToCloseTimeoutSeconds`
Specifies the `defaultExecutionStartToCloseTimeout` registered with Amazon SWF for the workflow type. This specifies the total time a workflow execution of this type may take to complete. See the *Amazon Simple Workflow Service API Reference* for more details.

`defaultTaskStartToCloseTimeoutSeconds`
Specifies the `defaultTaskStartToCloseTimeout` registered with Amazon SWF for the workflow type. This specifies the time a single decision task for a workflow execution of this type may take to complete. See the *Amazon Simple Workflow Service API Reference* for more details. The default is 30 seconds.

`defaultTaskList`
The default task list for the decision tasks for executions of this workflow type. The default can be overridden using `StartWorkflowOptions` when starting a workflow execution. Set to `USE_WORKER_TASK_LIST` by default. This is a special value which indicates that the task list used by the worker, which is performing the registration, should be used.

`defaultChildPolicy`
Specifies the policy to use for the child workflows if an execution of this type is terminated. The default value is `ABANDON`. The possible values are:

- `ABANDON`: Allow the child workflow executions to keep running
- `TERMINATE`: Terminate child workflow executions
- `REQUEST_CANCEL`: Request cancellation of the child workflow executions

@SkipRegistration

When used on an interface annotated with the `@Workflow` annotation, indicates that the workflow type should not be registered with Amazon SWF. One of `@WorkflowRegistrationOptions` and `@SkipRegistrationOptions` annotations must be used on an interface annotated with `@Workflow`, but not both.

@Signal

When used on a method in an interface annotated with the `@Workflow` annotation, identifies a signal that can be received by executions of the workflow type declared by the interface. Use of this annotation is required to define a signal method.

The following parameters can be specified on this annotation:

Name
: Specifies the name portion of the signal name. If not set, the name of the method is used.

@GetState

When used on a method in an interface annotated with the `@Workflow` annotation, identifies that the method is used to retrieve the latest workflow execution state. There can be at most one method with this annotation in an interface with the `@Workflow` annotation. Methods with this annotation must not take any parameters and must have a return type other than `void`.

@Activities

This annotation can be used on an interface to declare a set of activity types. Each method in an interface annotated with this annotation represents an activity type. An interface cannot have both `@Workflow` and `@Activities` annotations.

The following parameters can be specified on this annotation:

activityNamePrefix
: Specifies the prefix of the name of the activity types declared in the interface. If set to empty string (which is the default), the name of the interface followed by '.' is used as the prefix.

Version
: Specifies the default version of the activity types declared in the interface. The default value is 1.0.

dataConverter
: Specifies the type of the `DataConverter` to use for serializing/deserializing data when creating tasks of this activity type and its results. Set to `NullDataConverter` by default, which indicates that the `JsonDataConverter` should be used.

@Activity

This annotation can be optionally used on methods within an interface annotated with `@Activities`.

The following parameters can be specified on this annotation:

Name
: Specifies the name of the activity type. The default is an empty string, which indicates that the default prefix and the activity method name should be used to determine the name of the activity type (which

is of the form {*prefix*}{*name*}). Note that when you specify a name in an `@Activity` annotation, the framework will not automatically prepend a prefix to it. You are free to use your own naming scheme.

`Version`
Specifies the version of the activity type. This overrides the default version specified in the `@Activities` annotation on the containing interface. The default is an empty string.

@ActivityRegistrationOptions

Specifies the registration options of an activity type. This annotation can be used on an interface annotated with `@Activities` or the methods within. If specified in both places, then the annotation used on the method takes effect.

The following parameters can be specified on this annotation:

`defaultTasklist`
Specifies the default task list to be registered with Amazon SWF for this activity type. This default can be overridden when calling the activity method on the generated client using the `ActivitySchedulingOptions` parameter. Set to `USE_WORKER_TASK_LIST` by default. This is a special value which indicates that the task list used by the worker, which is performing the registration, should be used.

`defaultTaskScheduleToStartTimeoutSeconds`
Specifies the defaultTaskScheduleToStartTimeout registered with Amazon SWF for this activity type. This is the maximum time a task of this activity type is allowed to wait before it is assigned to a worker. See the *Amazon Simple Workflow Service API Reference* for more details.

`defaultTaskHeartbeatTimeoutSeconds`
Specifies the `defaultTaskHeartbeatTimeout` registered with Amazon SWF for this activity type. Activity workers must provide heartbeat within this duration; otherwise, the task will be timed out. Set to -1 by default, which is a special value that indicates this timeout should be disabled. See the *Amazon Simple Workflow Service API Reference* for more details.

`defaultTaskStartToCloseTimeoutSecond`
Specifies the defaultTaskStartToCloseTimeout registered with Amazon SWF for this activity type. This timeout determines the maximum time a worker can take to process an activity task of this type. See the *Amazon Simple Workflow Service API Reference* for more details.

`defaultTaskScheduleToCloseTimeoutSeconds`
Specifies the `defaultScheduleToCloseTimeout` registered with Amazon SWF for this activity type. This timeout determines the total duration that the task can stay in open state. Set to -1 by default, which is a special value that indicates this timeout should be disabled. See the *Amazon Simple Workflow Service API Reference* for more details.

@ManualActivityCompletion

This annotation can be used on an activity method to indicate that the activity task should not be completed when the method returns. The activity task will not be automatically completed and would need to be completed manually directly using the Amazon SWF API. This is useful for use cases where the activity task is delegated to some external system that is not automated or requires human intervention to be completed.

@Asynchronous

When used on a method in the workflow coordination logic, indicates that the method should be executed asynchronously. A call to the method will return immediately, but the actual execution will happen asynchronously when all Promise<> parameters passed to the methods become ready. Methods annotated with @Asynchronous must have a return type of Promise<> or void.

daemon
Indicates if the task created for the asynchronous method should be a daemon task. `False` by default.

@ExponentialRetry

When used on an activity or asynchronous method, sets an exponential retry policy if the method throws an unhandled exception. A retry attempt is made after a back-off period, which is calculated by the power of the number of attempts.

The following parameters can be specified on this annotation:

intialRetryIntervalSeconds
Specifies the duration to wait before the first retry attempt. This value should not be greater than `maximumRetryIntervalSeconds` and `retryExpirationSeconds`.

maximumRetryIntervalSeconds
Specifies the maximum duration between retry attempts. Once reached, the retry interval is capped to this value. Set to -1 by default, which means unlimited duration.

retryExpirationSeconds
Specifies the duration after which exponential retry will stop. Set to -1 by default, which means there is no expiration.

backoffCoefficient
Specifies the coefficient used to calculate the retry interval. Set to 2 by default. You can set this to 1 to get linear back-off or 0 to get a constant back-off.

maximumAttempts
Specifies the number of attempts after which exponential retry will stop. Set to -1 by default, which means there is no limit on the number of retry attempts.

exceptionsToRetry
Specifies the list of exception types that should trigger a retry. Unhandled exception of these types will not propagate further and the method will be retried after the calculated retry interval. By default, the list contains `Throwable`.

excludeExceptions
Specifies the list of exception types that should not trigger a retry. Unhandled exceptions of this type will be allowed to propagate. The list is empty by default.

@Wait and @NoWait

These annotations can be used on a parameter of type `Promise<>` to indicate whether the AWS Flow Framework for Java should wait for it to become ready before executing the method. By default, `Promise<>` parameters passed into `@Asynchronous` methods must become ready before method execution occurs. In certain scenarios, it is necessary to override this default behavior. `Promise<>` parameters passed into `@Asynchronous` methods and annotated with `@NoWait` are not waited for.

Collections parameters (or subclasses of) that contain promises, such as `List<Promise<Int>>`, must be annotated with `@Wait` annotation. By default, the framework does not wait for the members of a collection.

AWS Flow Framework for Java Exceptions

The following exceptions are used by the AWS Flow Framework for Java. This section provides an overview of the exception. For more details, see the AWS SDK for Java documentation of the individual exceptions.

ActivityFailureException

This exception is used by the framework internally to communicate activity failure. When an activity fails due to an unhandled exception, it is wrapped in `ActivityFailureException` and reported to Amazon SWF. You need to deal with this exception only if you use the activity worker extensibility points. Your application code will never need to deal with this exception.

ActivityTaskException

This is the base class for activity task failure exceptions: `ScheduleActivityTaskFailedException`, `ActivityTaskFailedException`, `ActivityTaskTimedoutException`. It contains the task Id and activity type of the failed task. You can catch this exception in your workflow implementation to deal with activity failures in a generic way.

ActivityTaskFailedException

Unhandled exceptions in activities are reported back to the workflow implementation by throwing an `ActivityTaskFailedException`. The original exception can be retrieved from the cause property of this exception. The exception also provides other information that is useful for debugging purposes, such as the unique activity identifier in the history.

The framework is able to provide the remote exception by serializing the original exception from the activity worker.

ActivityTaskTimedOutException

This exception is thrown if an activity was timed out by Amazon SWF. This could happen if the activity task could not be assigned to the worker within the require time period or could not be completed by the worker in the required time. You can set these timeouts on the activity using the `@ActivityRegistrationOptions` annotation or using the `ActivitySchedulingOptions` parameter when calling the activity method.

ChildWorkflowException

Base class for exceptions used to report failure of child workflow execution. The exception contains the Ids of the child workflow execution as well as its workflow type. You can catch this exception to deal with child workflow execution failures in a generic way.

ChildWorkflowFailedException

Unhandled exceptions in child workflows are reported back to the parent workflow implementation by throwing a `ChildWorkflowFailedException`. The original exception can be retrieved from the `cause` property of this exception. The exception also provides other information that is useful for debugging purposes, such as the unique identifiers of the child execution.

ChildWorkflowTerminatedException

This exception is thrown in parent workflow execution to report the termination of a child workflow execution. You should catch this exception if you want to deal with the termination of the child workflow, for example, to perform cleanup or compensation.

ChildWorkflowTimedOutException

This exception is thrown in parent workflow execution to report that a child workflow execution was timed out and closed by Amazon SWF. You should catch this exception if you want to deal with the forced closure of the child workflow, for example, to perform cleanup or compensation.

DataConverterException

The framework uses the `DataConverter` component to marshal and unmarshal data that is sent over the wire. This exception is thrown if the `DataConverter` fails to marshal or unmarshal data. This could happen for various reasons, for example, due to a mismatch in the `DataConverter` components being used to marshal and unmarshal the data.

DecisionException

This is the base class for exceptions that represent failures to enact a decision by Amazon SWF. You can catch this exception to generically deal with such exceptions.

ScheduleActivityTaskFailedException

This exception is thrown if Amazon SWF fails to schedule an activity task. This could happen due to various reasons—for example, the activity was deprecated, or an Amazon SWF limit on your account has been reached. The `failureCause` property in the exception specifies the exact cause of failure to schedule the activity.

SignalExternalWorkflowException

This exception is thrown if Amazon SWF fails to process a request by the workflow execution to signal another workflow execution. This happens if the target workflow execution could not be found—that is, the workflow execution you specified does not exist or is in closed state.

StartChildWorkflowFailedException

This exception is thrown if Amazon SWF fails to start a child workflow execution. This could happen due to various reasons—for example, the type of child workflow specified was deprecated, or a Amazon SWF limit on your account has been reached. The `failureCause` property in the exception specifies the exact cause of failure to start the child workflow execution.

StartTimerFailedException

This exception is thrown if Amazon SWF fails to start a timer requested by the workflow execution. This could happen if the timer Id specified is already in use or an Amazon SWF limit on your account has been reached. The `failureCause` property in the exception specifies the exact cause of failure to start the child workflow execution.

TimerException

This is the base class for exceptions related to timers.

WorkflowException

This exception is used internally by the framework to report failures in workflow execution. You need to deal with this exception only if you are using a workflow worker extensibility point.

AWS Flow Framework for Java Packages

This section provides an overview of the packages included with the AWS Flow Framework for Java.

com.amazonaws.services.simpleworkflow.flow.aspectj
Contains AWS Flow Framework for Java components that are required for features such as `@Asynchronous` and `@ExponentialRetry`.

com.amazonaws.services.simpleworkflow.flow.annotations
Contains the annotations used by the AWS Flow Framework for Java programming model.

com.amazonaws.services.simpleworkflow.flow.core
Contains core features such as `Task` and `Promise`.

com.amazonaws.services.simpleworkflow.flow
Contains components that integrate with Amazon SWF.

com.amazonaws.services.simpleworkflow.flow.common
Contains common utilities such as framework-defined constants.

com.amazonaws.services.simpleworkflow.flow.generic
Contains core components, such as generic clients, that other features build on.

com.amazonaws.services.simpleworkflow.flow.interceptors
Contains implementations of framework provided decorators including `RetryDecorator`.

com.amazonaws.services.simpleworkflow.flow.pojo
Contains classes that implement activity and workflow definitions for the annotation-based programing model.

com.amazonaws.services.simpleworkflow.flow.test
Contains helper classes, such as `TestWorkflowClock`, for unit testing workflow implementations.

com.amazonaws.services.simpleworkflow.flow.worker
Contains implementations of activity and workflow workers.

com.amazonaws.services.simpleworkflow.flow.junit.
Contains components that provide Junit integration.

com.amazonaws.services.simpleworkflow.flow.spring
Contains components that provide Spring integration.

Document History

The following table describes the documentation for this release of AWS Flow Framework for Java.

- **API version: 2012-01-25**
- **Latest documentation update: June 28, 2013**

Change	Description	Release Date
Documentation Update	The documentation has been corrected in a number of places due to customer feedback, and has been updated with setup instructions (p. 2) for the latest versions of Eclipse (4.3 "Kepler") and AWS SDK for Java (1.4.7) at the time of this release. The Introduction (p. 1) has been updated with a new set of walkthroughs that take the user step-by-step through building a number of Hello-world scenarios, each building upon the previous.	June 28, 2013
Initial Release	This is the initial public release of AWS Flow Framework for Java.	February 27, 2012
